Mercury cysteine S-conjugate
Methylmercury cysteine S-conjugate
Sulfur-containing amino acids

\textbf{A B S T R A C T}

Anthropogenic practices and recycling in the environment through natural processes result in release of potentially harmful levels of mercury into the biosphere. Mercury, especially organic forms, accumulates in the food chain. Mercury reacts readily with sulfur-containing compounds and often exists as a thiol S-conjugate, such as the l-cysteine (Cys)-S-conjugate of methylmercury (CH\textsubscript{3}Hg-S-Cys) or inorganic mercury (Cys-S-Hg-S-Cys). These S-conjugates are structurally similar to l-methionine and l-cystine/l-cystathionine, respectively. Bovine and rat glutamine transaminase K (GTK) catalyze transamination of sulfur-containing amino acids. Recombinant human GTK (rhGTK) has a relatively open catalytic active site, and we report here that this enzyme, like the rat and bovine enzymes, can also utilize sulfur-containing amino acids, including l-methionine, l-cysteine, and l-cystathionine as substrates. The current study extends this list to include mercuric S-conjugates, and shows that CH\textsubscript{3}Hg-S-Cys and Cys-S-Hg-S-Cys are substrates and reversible inhibitors of rhGTK. The homocysteine S-conjugates, Hcy-S-Hg-S-Hcy and CH\textsubscript{3}Hg-S-Hcy, are also inhibitors. Finally, we show that HgCl\textsubscript{2}, CH\textsubscript{3}Hg-S-Cys and Cys-S-Hg-S-Cys are potent irreversible inhibitors of rat cystathionine γ-lyase. The present study broadens our knowledge of the biochemistry of mercury compounds by showing that Cys S-conjugates of mercury interact with enzymes that catalyze transformations of biologically important sulfur-containing amino acids.

Introduction

Environmental mercury may exist in elemental (Hg\textsuperscript{0}), inorganic (Hg\textsuperscript{2+} or organic (Hg(I), Hg(II)) forms [1]. When mercury vapor (Hg\textsuperscript{0}) and Hg(II) compounds in the atmosphere settle into bodies of water, organic mercury (primarily monomethylmercury) is formed by cobalamin-dependent methylation, which is mediated by a variety of microorganisms [1]. For simplicity, monomethylmercury will be referred to as methylmercury in the current manuscript; however, it is important to note that methylmercury, in aqueous solutions, often reacts with anions such as Cl\textsuperscript{−} to form covalent bonds [2].

Methylmercury accumulates readily in tissues of numerous aquatic organisms, especially large, predatory fish [1]. It is the predominant form of organic mercury in the environment and humans are exposed to this organometallic species primarily via consumption of contaminated fish and/or water [1–3]. Inasmuch as methylmercury exposure can be detrimental to multiple tissues and organs, including the brain and kidneys, it is recommended that certain species of fish, particularly those at the top of the food chain, be consumed sparingly, especially by pregnant women and young children [4–8]. Despite this recommendation, 6–8% of women of child-bearing age in the US may have unacceptably high levels of mercury [7,8]. Because of high lipid solubility, methylmercury can readily cross the placenta and accumulate in fetal tissues [1], thus raising the possibility that a sizable population of newborns may be exposed to mercury in utero.

Because of concerns about the toxicity of mercury, it is important to identify the forms of mercury capable of being transported by target organs and cells. Mercuric ions have a strong bonding affinity for reduced sulfur atoms [9]. Consequently, mercuric ions within biological systems are converted primarily to conjugates of one or more sulfur (thiol)-containing biomolecules, such as
glutathione (GSH),\textsuperscript{2} L-cysteine (Cys), and L-homocysteine (Hcy). Some of these mercury conjugates are similar structurally to certain endogenous amino acids [10–12]. For example, the structure of the Cys S-conjugate of methylmercury (i.e. CH$_3$Hg-S-Cys) is similar to that of methionine (Fig. 1). CH$_3$Hg-S-Cys may be formed by direct reaction of Cys with methylmercury. Alternatively, methylmercury may react with GSH to form a glutathione S-conjugate (i.e. CH$_3$Hg-S-G), which can then be catabolized to CH$_3$Hg-S-Cys by the sequential actions of $\gamma$-glutamyltransferase and cysteinylglycinase/amino-peptidase M located in the luminal membranes of intestinal and renal epithelial cell [11,13] (Fig. 2). Due to the presence of a large hydrophobic side group and structural similarity to methionine, CH$_3$Hg-S-Cys may be transported into cells via the amino acid transporter, system L [13]. This transporter has an affinity for large hydrophobic amino acids, including L-methionine [13].

The similarity between CH$_3$Hg-S-Cys and methionine has been suggested by a number of authors [14–16] to be an example of “molecular mimicry” whereby CH$_3$Hg-S-Cys is a mimic of methionine at the site of the system L transporter. Molecular mimicry has been defined as the phenomenon whereby one molecule/compound can act as a structural and/or functional molecule of another endogenous molecule/compound [11,15]. However, the concept that cysteine S-conjugates of mercury are molecular mimics of sulfur-containing amino acids has been criticized by Hoffmeyer and colleagues [17]. These authors' definition of molecular mimicry is restricted to isosteric compounds with similar electronic distributions [17]. Here, we simply point out the similarities between the cysteine S-conjugates of mercury and other amino acids, including sulfur-containing amino acids.

Following ingestion of methylmercury, there is evidence indicating that some of these species undergoes biotransformation in intracellular or extracellular compartments to yield inorganic mercury [3]. Thus, thiol-S-conjugates of both Hg$^{2+}$ and methylmercury may be present in target cells and organs of biological systems. Interestingly, the Cys-S-conjugate of Hg$^{2+}$ (i.e. Cys-S-Hg-S-Cys), which is similar structurally to L-cysteine (Fig. 1) and L-cystathionine) and Hcy-S-Hg-S-Hcy (similar to L-homocysteine) is taken up at the luminal membrane of renal proximal tubular cells by the amino acid transporter, system b$_0$,\textsuperscript{0} [18–20]. System b$_0$,\textsuperscript{0} is an important absorptive transporter of L-cystine. In addition, the glutathione S-conjugate of Hg$^{2+}$ (G-S-Hg-S-G) is similar structurally to

---

\textsuperscript{2} Abbreviations used: CH$_3$Hg-S-Cys, L-cysteine S-conjugate of methylmercury; CH$_3$Hg-S-Hcy, L-homocysteine S-conjugate of methylmercury; Cys-S-Hg-S-Cys, L-cysteine S-conjugate of inorganic mercury; DTT, dithiothreitol; GTK, glutamine transaminase K; GSH, glutathione; G-S-Hg-S-G, glutathione S-conjugate of inorganic mercury; GSSG, glutathione disulfide; Hcy-S-Hg-S-Hcy, L-homocysteine S-conjugate of inorganic mercury; KAT L, lynurenine aminotransferase isozyme 1; KMB, a-keto- $\gamma$- methylbutyrate; MPA, metaphosphoric acid; PLP, pyridoxal 5’-phosphate; rhGTK, recombinant human GTK.
glutathione disulfide (GSSG) and may be a substrate/inhibitor of proteins that interact with GSSG. GSSG is critical for post-translational modification of proteins involved in redox signaling [21,22].

Given that thiol-S-conjugates of Hg2+ and methymercury are similar structurally to endogenous compounds, we hypothesized that these conjugates may also function as substrates of certain intracellular enzymes (in addition to the membrane-bound external enzymes γ-glutamyltransferase and cysteinylglycinase/aminopeptidase M). To investigate this possibility we chose to study the interaction of Cys- and Hcy-S-conjugates of Hg2+ and methymercury with kidney glutamine transaminase K [GTK; also known as kynurenine aminotransferase isozyme I (KAT I)] and cystathionine γ-lyase (γ-cystathionase). The rationale for these investigations evolved from the observation that rat kidney GTK utilizes α-amino acid and α-keto acid substrates of the general structure \( Y(\text{CH}_2)_n\text{CH}[\text{NH}_3]^+\text{CO}_2^- \) and \( Z(\text{CH}_2)_m\text{C}(\text{O})\text{CO}_2^- \), respectively, where \( n = 1 \) or 2 and \( Y \) (or \( Z \)) is generally a hydrophobic or uncharged moiety that can be relatively large [23,24] (Fig. 3, Eq. (1)). (An exception is cysteine and some other sulfur-containing amino acids where \( Y \) possesses a terminal charged grouping.) Thus, for example, rat kidney GTK catalyzes transamination with L-glutamine (as the name implies), L-methionine and L-phenylalanine, and their corresponding α-keto acids [23,24]. Glutamine transaminases purified from bovine kidney [25] and brain [26] exhibit activity toward L-glutamine, L-methionine and L-phenylalanine, but also toward large sulfur-containing amino acids (e.g. L-cystine, L-homocysteine and L-cystathionine). Highly purified rat kidney GTK exhibits activity toward L-cystine, L-homocysteine, L-cystathionine and L-lanthionine when phenylpyruvate is used as the co-substrate (amine acceptor) [27].

X-ray crystallographic studies of recombinant human GTK/KAT I (rhGTK) have shown that this enzyme has a remarkably open configuration at the active site. The enzyme substrate binding site possesses a striking crown of aromatic residues that adorns the relatively large active site [28]. Although turnover is somewhat slow, rhGTK was shown to catalyze transamination of two positional isomers of β-naphthyl-L-alanine [29], consistent with a large, relatively open active site. Fig. 4 depicts a ribbon model of hGTK monomer (the active enzyme is a homodimer) showing the position of the pyridoxal 5'-phosphate (PLP) coenzyme bound in Schiff base linkage (internal aldimine) to a lysine residue in the active site. Surface representations of the monomer reveal that the active site is spacious (Fig. 4). Fig. 4 also illustrates the positions of all six cysteine moieties within the monomer. It is readily apparent that the active site does not contain a cysteine residue. One cysteine residue (C127) is 6.8 Å away from the PLP coenzyme; other cysteine residues are 12.5–20.4 Å away from the coenzyme epicenter.

Transamination of L-cystathionine, L-lanthionine, and L-cystine in vitro yields α-keto acids that can non-enzymatically cyclize to ketimines (reviewed in [24,30]). Some of these compounds and their reduced forms (cyclic amines) have been reported to be present in brain, plasma and/or urine and may be neuroactive (discussed in [24]). Furthermore, GTK activity is present in human brain [31]. Therefore, GTK may be responsible for generating sulfur-containing neuroactive cyclic ketimines in human brain. Because the active site of rhGTK is large [28], it is also possible that the enzyme will catalyze transamination in human tissues with thiol-S-conjugates of Hg (Fig. 3, Eq. (1) where \( n = 1 \) or 2, and \( Y = \text{CH}_3\text{HgS}^- \) or \( \text{Cys}–\text{HgS}– \)). This hypothesis is supported by the finding that 6-methyl-L-selenocysteine is a substrate of rhGTK [29] and this conjugate and other selenocysteine S-conjugates, many of which contain large aromatic moieties, are substrates of rat GTK [32]. On the other hand, whereas 6-methyl-L-selenocysteine and L-methionine are relatively good substrates of rhGTK, the closely related amino acid, L-selenomethionine, is an extremely poor substrate (<0.1% as effective as L-methionine) [29]. Thus, due to these subtleties in binding geometries it was not certain a priori that the enzyme would catalyze transamination of thiol-S-conjugates, despite the relatively open active site. The present work, however, does indeed show that rhGTK catalyzes transamination
of large sulfur-containing amino acids as well as the Cys-S-conjugates of Hg\textsuperscript{2+} and methylmercury.

We next turned our attention to cystathionine \(\gamma\)-lyase. This enzyme catalyzes a \(\gamma\)-lyase reaction with \(\gamma\)-cystathionine, generating \(\alpha\)-ketobutyrate, cysteine (eliminated fragment) and ammonia (Fig. 3, Eq. (2)). \(L\)-Homoserine is also a \(\gamma\)-lyase substrate, generating \(\alpha\)-ketobutyrate and ammonia (Fig. 3, Eq. (3)). In this case the hydrolysis reaction is balanced by elimination of H\(_2\)O. Thus, the net reaction does not include an H\(_2\)O term. The enzyme can also catalyze a \(\beta\)-lyase reaction with \(\gamma\)-cystine (Fig. 3, Eq. (4)), generating pyruvate, the persulfide analogue of cysteine (thiocysteine) and ammonia [33,34].

Rat liver cystathionine \(\gamma\)-lyase has a cysteine residue within the active site [35] that is highly susceptible to inactivation by a number of sulfhydryl reagents including \(p\)-chloromercuribenzoate, iodosobenzoate and \(N\)-ethylmaleimide [36,37]. Therefore, we considered the possibility that Cys-S-conjugates of mercury, particularly Cys-S-Hg-S-Cys, would interact with this sulfhydryl in the active site of cystathionine \(\gamma\)-lyase. The present work shows that Cys-S-Hg-S-Cys is a strong irreversible inhibitor of cystathionine \(\gamma\)-lyase.

Materials and methods

Reagents

Methylmercuric chloride (\(CH_3\text{HgCl}\)) and HgCl\(_2\) were obtained from Aldrich, Milwaukee, WI. Mercuric-S-conjugates were generated by mixing HgCl\(_2\) with Cys or Hcy in a 1:2.5 ratio. Methylmercury S-conjugates were generated by mixing \(CH_3\text{HgCl}\) with Cys or Hcy in a 1:1.25 ratio. The conjugates were incubated for five minutes at room temperature prior to use. Ammediol (2-amino-2-methyl-1, 3-propanediol), dithiothreitol (DTT), GSH, sulfur-containing amino acids, \(\gamma\)-glutamine, \(\gamma\)-phenylalanine, \(\gamma\)-homoserine, phenylpyruvate, sodium \(\alpha\)-keto-\(\gamma\)-methiolbutyrate [sodium \(\alpha\)-keto-(\(\gamma\)-methylthio)butyrate; KMB] were obtained from Sigma, St. Louis, MO. 2,4-Dinitrophenylhydrazine was purchased from MP Biochemicals, Irvine, CA.

Enzymes

Highly purified rhGTK [1.8 mg/ml in 20% glycerol, 10 mM potassium phosphate buffer (pH 7.4); specific activity 18 U/mg in the standard reaction assay mixture, see below] was obtained by the method of Han et al. [38]. Cystathionine \(\gamma\)-lyase (specific activity 24 U/mg, 20 mM \(L\)-homoserine as substrate) was purified from rat liver as described by Pinto et al. [39]. One unit of enzyme activity is the amount of enzyme that generates 1 \(\mu\)mol of product per min at 37 °C under standard reaction conditions.

Enzyme activity measurements

The standard GTK assay mixture (50 \(\mu\)l) contained 100 mM ammediol buffer (pH 9.0), 5 mM KMB and 20 mM \(L\)-phenylalanine [40]. After incubation at 37 °C (5–10 min), 150 \(\mu\)l of 1 M NaOH was added and the absorbance at 322 nm due to phenylpyruvate enol (\(\epsilon_{322\text{nm}} = 16,000 \text{ M}^{-1} \text{ cm}^{-1}\)) was determined within 5 min against a blank consisting of complete reaction mixture lacking enzyme. The activity of rhGTK in a reaction mixture containing 100 mM potassium phosphate buffer (pH 7.4) in place of ammediol buffer in the standard reaction mixture is \(~\)50% that exhibited at pH 9.0 [29]. The standard cystathionine \(\gamma\)-lyase assay mixture (50 \(\mu\)l) contained 100 mM potassium phosphate buffer (pH 7.4) and 20 mM \(L\)-homoserine [39]. After incubation at 37 °C (10 min), the reaction...
was stopped by addition of 20 μl of 5 mM 2,4-dinitrophenylhydrazine in 2 M HCl. After further incubation at 37 °C for 10 min, 130 μl of 1 M NaOH was added and the absorbance was read within 5 min at 430 nm against a blank consisting of reaction mixture lacking \( \text{L-homoserine (or enzyme)} \) (4-keto-2,4-dinitrophenylhydrazone, 15,000 M⁻¹ cm⁻¹). To measure aminotransferase activity of GTK toward various amino acids (other than the mercury S-conjugates) the reaction mixture (50 μl), except where noted, contained 100 mM potassium phosphate buffer (pH 7.4), 1.0 mM \( \text{L-amino acid (50 nmol)} \) and 0.4 mM phenylpyruvate (20 nmol) and GTK. In the case of \( \text{L-cystine} \) the concentration was 0.4 mM and the buffer was 50 mM sodium pyrophosphate, pH 9.2. The reaction mixture was incubated at 37 °C and the amount of phenylpyruvate remaining was determined (as described above) against a blank containing complete reaction mixture lacking enzyme. A similar procedure was used to measure the rhGTK-catalyzed transamination of mercury S-conjugates, except that the concentration of phenylpyruvate was 0.2 mM. Blanks contained the complete reaction mixture (including mercuric conjugates) without enzyme.

Spectrophotometric determinations were conducted with a Tecan Infinite M1000 96-well plate spectrophotometer (Tecan, Durham, NC) or with a SpectraMax 96-well plate spectrophotometer (Molecular Devices, Sunnyvale, CA).

**HPLC measurement of \( \text{L-methionine} \) and KMB**

The HPLC system consisted of a liquid chromatograph equipped with an 8-channel coulometric array (CoulArray) detector (ESA, Inc., Chelmsford, MA) [39,41]. The enzyme activity in the reaction mixtures (50 μl) was terminated by addition of 15 μl of 25% w/v metaphosphoric acid (MPA). The resulting 5% w/v MPA homogenates were injected directly onto a Bio-Sil ODS-5S, 5-μm particle size, 4.0 × 250 mm, C18 column (Bio-Rad, Life Science Research Group, Hercules, CA) and eluted with a mobile phase consisting of 50 mM NaH₂PO₄, pH 2.52 at a flow rate of 1 ml/min. All buffers, following preparation, were routinely degassed, filtered through a 0.2-μm Millipore nylon filter, and the pH re-adjusted, if necessary. PEEK™ (polyetheretherketone) tubing was used throughout the HPLC system, and a 0.2-μm PEEK™ filter was placed pre- and post-column to protect both column and flow cells, respectively, from any particulate matter. A Rhodyne injection valve with a 5-μl sample loop was used to manually introduce samples. The 8-channels of the CoulArray detector were set at 100, 200, 300, 400, 500, 600, 700 and 800 mV, respectively. Elution times (min) and detection potential ranges (mV) are: MPA (1.6), \( \text{L-methionine (9.6, 600–800 mV)} \) and KMB (11.1, 600–800 mV). Other sulfur-containing compounds eluted at times that did not interfere with analysis of \( \text{L-methionine} \) or KMB.

**Data analyses**

For measurements of the effect of HgCl₂ and \( \text{CH₃} \text{HgCl} \) on the rhGTK-catalyzed transamination of \( \text{L-phenylalanine} \) with KMB, differences between two means were analyzed using the Mann– Whitney \( U \) test. For measurements of inactivation of cystathionine \( \gamma \)-lyase by various mercury-conjugating compounds, differences among means were analyzed using a two-way Analysis of Variance, followed by Tukey’s post hoc testing. Each set of respective data was analyzed first with the Kolmogorov–Smirnov test for normality, followed by the Levene test for homogeneity of variances. A \( p \)-value of <0.05 was considered statistically significant. Data are presented as the mean ± SD. Except where noted, measurements were carried out at least in triplicate.
two determinations) with various amino substrates was as follows: L-glutamine (16.0), L-cystine (1.4), L-cystathionine (0.9), L-lanthionine (0.6). The formation of L-methionine in reaction mixtures containing L-glutamine was accompanied by an approximately equimolar loss of KMB.

The values for rhGTK-catalyzed transamination of L-cystine and L-cystathionine with KMB are somewhat lower than those obtained with phenylpyruvate as an α-keto acid substrate. As was previously demonstrated for bovine [26] and rat kidney [27] glutaminin transaminases, the critical issue here is that rhGTK catalyzes transamination of L-methionine, L-cystine and L-cystathionine with suitable α-keto acid acceptors. Thus, because CH₃Hg-S-Cys and Cys-S-Hg-S-Cys are similar to L-methionine and L-cystine/L-cystathionine insofar as both conjugates contain sulfur and a relatively large side group, we considered the possibility that CH₃Hg-S-Cys and Cys-S-Hg-S-Cys would be substrates and/or inhibitors of rhGTK.

**Inhibition of rhGTK by mM concentrations of HgCl₂ and CH₃HgCl**

As discussed below, cystathionine γ-lyase is strongly inhibited by μM (or less) concentrations of mercury-containing compounds. By contrast our results show that rhGTK, despite the fact that both enzymes contain cysteine residues, is much more resistant to inhibition. Fig. 6 shows the time course for phenylpyruvate production by rhGTK-catalyzed transamination at 37 °C in a reaction mixture (50 μl) containing 2.6 μM rhGTK, 5 mM KMB, 20 mM L-phenylalanine, and 100 mM potassium phosphate buffer (pH 7.4). The transamination reaction is freely reversible (Fig. 3, Eq. (1)). Thus, the slower reaction rate at 60 min relative to the initial rate is presumably a result of the back reaction competing with the forward reaction. When 10 μM HgCl₂ or 10 μM CH₃HgCl was included in the reaction mixture no difference in the rate of phenylpyruvate formation compared to the control was noted (data not shown). However, when 1 mM HgCl₂ or 1 mM CH₃HgCl was included in the reaction mixture transamination of L-phenylalanine was inhibited at all time points relative to the control that lacked mercury compound (Fig. 6).

One possible explanation for the findings is that slow binding of Hg²⁺ and CH₃HgCl to the enzyme occurred over a 20 min period followed by establishment of a greatly slowed transamination rate between 30 and 60 min. However, due to the nature of the plot shown in Fig. 6 it was difficult to discern whether there was still some residual enzyme activity at 60 min or at later time points. Therefore, to investigate the possibility of residual activity in enzyme exposed to Hg²⁺ or CH₃HgCl, rhGTK (∼2.6 mU) was incubated in complete reaction mixture (50 μl) lacking KMB in the presence or absence of 1 mM CH₃HgCl. After incubation for 1 h at 37 °C, transamination was initiated by addition of 2.5 μl of 100 mM KMB. After a further incubation for 30 min at 37 °C, the formation of phenylpyruvate was measured. The amount of phenylpyruvate formed by rhGTK that was exposed to 1 mM CH₃HgCl for 1 h was 11.7 ± 2.1% relative to the control (100 ± 13%) (n = 6). A similar experiment was carried out with HgCl₂. In this case, the amount of phenylpyruvate formed by rhGTK that was exposed to 1 mM HgCl₂ for 1 h was 6.9 ± 1.5% relative to the control (100 ± 10%) (n = 6).

There are at least two possible explanations for the findings of residual activity in rhGTK exposed to CH₃HgCl or Hg²⁺. First, binding of the mercury compound causes 100% irreversible inactivation, but 5–10% of the enzyme population is resistant to binding of the mercury compound and remains fully active. Secondly, 100% of the enzyme is strongly modified within about 20 min and all modified enzyme species are active, albeit at a reduced efficiency. To distinguish between the two possibilities, 0.6 μl of enzyme was incubated for 1 h at 37 °C in 40 μl of 100 mM potassium phosphate buffer (pH 7.4) containing 0.5, 1 or 2 mM HgCl₂. Thereafter, L-phenylalanine and KMB were added to yield final concentrations of 20 mM and 5 mM, respectively (final volume 50 μl). After an additional 30-min incubation at 37 °C, the amounts of phenylpyruvate formed were 8.96 ± 0.66, 1.42 ± 0.42, 0.76 ± 0.26, and 0.52 ± 0.20 nmol, respectively (n = 3). In another series of experiments, 0.6 μl of enzyme was incubated for an hour at 37 °C in 40 μl of 100 mM potassium phosphate buffer (pH 7.4) containing 2 mM HgCl₂. Thereafter, 5 μl of 100 mM DTT was added and the mixture was incubated for 30 min at 37 °C. Then, 10 μl of 100 mM L-phenylalanine and 5 μl of 100 mM KMB were added (final volume 55 μl). After an additional 30-min incubation at 37 °C, phenylpyruvate was measured. The amount of phenylpyruvate formed was 7.12 ± 0.16 nmol (n = 3). Thus, after addition of a 6.25-fold molar excess of DTT over that of HgCl₂, the inhibition by Hg²⁺ was largely (∼80%) reversed.

The data suggest that reaction with mM concentrations of Hg²⁺ ions or CH₃HgCl is a relatively slow process, but that the interaction eventually substantially lowers the activity of rhGTK. The activity, however, can be largely restored by treatment with DTT. Possibly, covalent binding of the mercury species to one or more cysteine sulfhydryls alters the conformation of the enzyme so that the enzyme cannot bind substrate or binds substrate much less effectively. The DTT restores the original sulfhydryl groups with recovery of activity. Alternatively, S-Hg exchange involving DTT results in an Hg conjugate that can no longer bind to the enzyme. As shown below, the results are in marked contrast to those obtained with cystathionine γ-lyase, where the enzyme is rapidly and irreversibly inactivated by μM (or lower) concentrations of HgCl₂, Cys-S-Hg-S-Cys and CH₃Hg-S-Cys. It should be noted that the use of mM concentrations of mercuric species is not biologically relevant. The experiments were designed to show the markedly different susceptibility of cystathionine γ-lyase to various forms of mercury compared to GTK despite the fact that both enzymes utilize sulfur-containing amino acids as substrates and possess cysteine residues.

**rhGTK-catalyzed transamination of CH₃Hg-S-Cys and Cys-S-Hg-S-Cys**

As noted above, CH₃Hg-S-Cys and Cys-S-Hg-S-Cys were hypothesized to be substrates of GTK. In order to provide evidence for this hypothesis, enzyme-catalyzed disappearance of phenylpyruvate was measured in a reaction mixture containing 2.6 μl rhGTK, 0.2 mM phenylpyruvate, 1 mM mercury S-conjugate and 100 mM potassium phosphate buffer (pH 7.4). The corresponding
homocysteine S-conjugates were included for comparison. Lower concentrations of phenylpyruvate were included in this experiment compared to those used to determine the substrate specificity toward physiologically important sulfur-containing amino acids (Fig. 5). Significant disappearance of absorbance of phenylpyruvate (enol) relative to the blank should be more readily apparent at lower concentrations of phenylpyruvate. The low phenylpyruvate concentration in this experiment (0.2 mM) should not be limiting for enzyme activity because rat kidney GTK (and presumably rhGTK) has a high affinity for phenylpyruvate [23].

No significant rhGTK activity was detected with 1 mM Hcy-S-Hg-S-Hcy (Fig. 7). The enzyme appears to have some activity with the homocysteine derivative, CH3Hg-S-Hcy, but the activity value did not quite reach significance. On the other hand, significant enzymatic activity was found with the cysteinyl derivatives, Cys-S-Hg-S-Cys and CH3Hg-S-Cys (Fig. 7).

Inhibition of rhGTK activity by Cys-S-Hg-S-Cys, Hcy-S-Hg-S-Hcy, CH3Hg-S-Cys and CH3Hg-S-Hcy

Because CH3Hg-S-Cys and Cys-S-Hg-S-Cys have similarities with methionine and cysteine/cystathionine, respectively, and are substrates of rhGTK, they were predicted to be inhibitors of the enzymatic activity was found with the cysteinyl derivatives, Cys-S-Hg-S-Cys and CH3Hg-S-Cys (Fig. 7).

Inhibition of rat liver cystathionine γ-lyase by μM concentrations of HgCl2, Cys-S-Hg-S-Cys and CH3Hg-S-Cys

As noted above, cystathionine γ-lyase catalyzes a β-elimination reaction with γ-cystine in a reaction that generates pyruvate ([33,34]; Fig. 3, Eq. (4)). Therefore, we considered the possibility that the enzyme might be able to catalyze pyruvate formation from Cys-S-Hg-S-Cys and CH3Hg-S-Cys. However, we were unable to detect pyruvate formation (as the 2,4-dinitrophenylhydrazone derivative) within the sensitivity of the assay (~0.2 nmol), when 1 μM cystathionine γ-lyase was incubated for 1 h at 37 °C in a reaction mixture containing varying concentrations of L-phenylalanine, 5 mM potassium phosphate buffer (pH 7.4) and enzyme (2 μU) in a final volume of 50 μl in the presence or absence of Cys-S-Hg-S-Cys (1 mM) or CH3Hg-S-S-Cys or CH3Hg-S-Hcy and the amount of pyruvate produced was determined. The relative amounts of pyruvate formed at three concentrations of L-phenylalanine, ranging from 10 mM (a concentration slightly above the Km value) to 50 mM (a concentration considerably above the Km value) in the presence and absence of various mercury S-conjugates are shown in Table 1. This table shows that, under the conditions of the assay, the mercury S-conjugates, at a concentration of 0.5–1 mM, are strongly inhibitory. Because Cys-S-Hg-S-Cys and CH3Hg-S-S-Cys are substrates of rhGTK (Fig. 7) part of the inhibition noted with these two compounds must be competitive with respect to L-phenylalanine. If the inhibition, however, were strictly competitive then the relative inhibition would be less as the concentration of L-phenylalanine was increased relative to the concentration of conjugate. This was not the case for these two conjugates and also for Hcy-S-Hg-S-Hcy and CH3Hg-S-Hcy. In fact, within experimental error there was little change in the degree of inhibition exerted by the mercury S-conjugates from 10 to 50 mM L-phenylalanine (Table 1). This finding suggests a strong noncompetitive component. However, it was not possible to carry out kinetic experiments with concentrations of mercury S-conjugates at concentrations >1 mM because this is the limit of the solubility of these conjugates. Moreover, the non-linearity of the reaction over the 30 min incubation (Fig. 6) complicates interpretation of data. The exact type of inhibition remains to be determined, but it is worth noting that the mercury conjugates appear to bind more strongly to rhGTK (strong inhibition at ≤1 mM) than L-phenylalanine (Km ~7.6 mM).

The reaction mixture contained varying concentrations of L-phenylalanine, 5 mM KMB, 100 mM potassium phosphate buffer (pH 7.4) and enzyme (2 μU) in a final volume of 50 μl in the presence or absence of mercapturic acid (Fig. 3, Eq. (4)). Therefore, we considered the possibility that the enzyme might be able to catalyze pyruvate formation from Cys-S-Hg-S-Cys and CH3Hg-S-Cys. However, we were unable to detect pyruvate formation (as the 2,4-dinitrophenylhydrazone derivative) within the sensitivity of the assay (~0.2 nmol), when 1 μM cystathionine γ-lyase was incubated for 1 h at 37 °C in a reaction mixture containing varying concentrations of L-phenylalanine, 5 mM KMB, 100 mM potassium phosphate buffer (pH 7.4) and enzyme (2 μU) in a final volume of 50 μl in the presence or absence of mercapturic acid. After incubation for 2 h at 37 °C the disappearance of phenylpyruvate was measured in comparison to a blank lacking enzyme; ND not detectable. aNot significantly different from the blank values (n = 5).
mixture (50 μl) containing 1 mM Cys-S-Hg-S-Cys (or CH3Hg-S-Cys) and 100 mM potassium phosphate buffer, pH 7.4.

As also noted above, rat liver cystathionine γ-lyase was previ-
ously shown to be highly susceptible to inactivation by a number of sulfhydryl reagents including p-chloromercuribenzoate. This reaction and that with HgCl2 are formally depicted below, where P = protein. Thus, it was predicted that HgCl2 would also be a
strong inactivator of cystathionine γ-lyase and this was found to be the case (see below).

**PSH + CHgAr → PSHgAr + HCl**

**PSH + CHgCl → PSHgCl + HCl**

The previous findings with p-chloromercuribenzoate [36] and the present findings with HgCl2 indicate that the active site cysteine is reactive. It was then of interest to determine whether this reactive cysteine residue can interact with mercury cysteine conjugates that are substrate analogues. If the conjugates bind simply as substrate analogues then it is expected that they will be irreversible inhibitors. However, if they can bind in such a manner as to come in close contact with this reactive cysteine residue then it was predicted that the mercury cysteine conjugates would be strong irreversible inhibitors of the enzyme. This was found to be the case.

When the effect of various mercury-containing compounds on the activity of purified rat liver cystathionine γ-lyase was determined, significant inhibition of cystathionine γ-lyase occurred when μM amounts of these compounds were added to the standard reaction mixture containing 20 mM L-homoserine (Fig. 8). (L-Homo-
sine (Km = 20 mM) [42] is used in routine analytical assays for cystathionine γ-lyase (Fig. 3, Eq. (3)).) Interestingly, the extent to which inactivation occurred with the various mercury-containing com-
ounds was as follows: Cys-S-Hg-S-Cys > HgCl2 > CH3Hg-S-Cys. Pos-
sibly, the difference between Cys-S-Hg-S-Cys and CH3Hg-S-Cys reflects the fact that Cys-S-Hg-S-Cys bears closer resemblance to the substrates L-cystathionine and L-cystine than does CH3Hg-S-
Cys. CH3Hg-S-Cys resembles methionine, which is not a cystathio-
nine γ-lyase substrate. It should be noted that the amount of mer-
cury present in the 50-μl reaction mixture at the lowest concentration (0.2 μM) was 10 pmol. Based on the specific activity of cystathionine γ-lyase and the fact that the enzyme is a homotrimer (subunit Mr ~44,000), the amount of cystathionine γ-lyase monomers in the incubation mixture was 75 fmol. Thus, the mercury-containing compounds were in large excess over cystathionine γ-lyase in these experiments. Another point of concern is whether the mercury-containing compounds interfere with the 2,4-dinitrophenylhydrazine assay for the quantitation of pyruvate (β-lyase reaction) or α-ketobutyrate (standard cystathionine β-lyase reaction). In control experiments it was shown that the presence of 2 mM HgCl2 or 2 mM Cys-S-Hg-S-Cys had no effect on the yield of α-keto acid 2,4-dinitrophenylhydrazone when standard cystathio-
nine γ-lyase reaction mixtures (0.05 ml) were spiked with 10 nmol pyruvate and incubated at 37 °C for 1 h followed by a further 10 min incubation with the 2,4-dinitrophenylhydrazine reagent.

The present findings suggest that positioning a mercuric S-conju-
gate as a substrate analogue in close proximity to the active site of cystathionine γ-lyase facilitates modification of the cysteine moiety within the enzyme active site. Despite the fact that the S–Hg bond has a high stability constant (~0.22 kJ/mol) [9,43], the coordination bonds of mercury are kinetically quite labile [43–45]. Thus, the greater potency of Cys-S-Hg-S-Cys compared to HgCl2 as an inactivator of cystathionine γ-lyase (Fig. 7) may be due to binding of Cys-
S-Hg-S-Cys as an analogue of L-cystathionine-L-cystine followed by a rapid S-Hg exchange reaction with a protein-bound cysteine moiety within the active site of the enzyme.

In a separate set of experiments, 2.1 μl of cystathionine γ-lyase was incubated for 1 h at 37 °C in the presence of 100 mM potassium phosphate buffer (pH 7.4) and 20 μM of either HgCl2 or Cys-S-Hg-S-Cys (final volume 20 μl). At the end of the incubation 1 M potassium phosphate (pH 7.4) and 100 mM L-homoserine were added, such that the final volume was 50 μl and the concentrations of buffer and L-homoserine were 100 mM and 20 mM, respectively. After an additional 30-min incubation at 37 °C, α-ketobutyrate formation was measured. Only 5% of the activity relative to a control (2.1 μl of enzyme incubated in phosphate buffer in the absence of mercury compound) was detected for enzyme protein that had been exposed to HgCl2, whereas no activity could be detected with enzyme that had been exposed to Cys-S-Hg-S-Cys. In both cases, addition of DTT to a final concentration of 5 mM did not restore any enzyme activity, even after incubation for 5 h at 37 °C. However, the choice of DTT in this experiment may not have been optimal. For example, it is known that in the case of bacterial MerB (organomercurial lyase; catalyzes the reaction: RHg(II) → RH + Hg(II)), DTT binds to the Hg-S enzyme adduct to form a stable 3-coordinate Hg complex [46,47]. Therefore, the experiment was repeated to determine whether 20 mM cysteine or 20 mM GSH (final concentration) in place of DTT could reactivate enzyme that had been inactivated by HgCl2 or Cys-S-Hg-S-Cys. No activity was restored after incubation of HgCl2- or Cys-S-Hg-S-Cys-inactivated enzyme for two hours at 37 °C in the presence of 20 mM L-cysteine or 20 mM GSH.

**Discussion**

As mentioned in the Introduction, L-methionine, L-cystine and L-
cystathionine are substrates of rat kidney GTK. Consistent with this finding, the present work shows that these sulfur-containing amino acids are also substrates of the human counterpart (rhGTK) (Fig. 5). Moreover, this work also shows that the sulfur-containing mercury conjugates Cys-S-Hg-S-Cys and CH3Hg-S-Cys are transami-
nine substrates of this enzyme (Fig. 7). The ability to transamine these conjugates presumably is a result in part of the relatively open active site and the ability of the enzyme to utilize large amino acid substrates. However, under the conditions of our assay these mercury conjugates are not as active as the “natural” in vivo substrates L-glutamine, L-cysteine, L-methionine and L-phenylalanine.
The question arises as to whether these transamination reactions with Cys-S-Hg-S-Cys and CH3Hg-S-Cys are biologically relevant. Transamination of Cys-S-Hg-S-Cys and CH3Hg-S-Cys was demonstrated at 1 mM concentration, but it is doubtful that this concentration could be attained in vivo even after severe mercury poisoning. Moreover, there will be strong competition with endogenous amino acid substrates naturally present at much higher concentrations. However, aminotransferases generally exhibit $K_m$ values in the mM or tens of mM range and this is true of GTK ([38]; present work). Thus, it is possible that GTK is not fully saturated with endogenous amino acid substrates and that some binding of Cys-S-Hg-S-Cys and CH3Hg-S-Cys will occur even when these conjugates are present at low concentrations. There is precedent for transamination of a metabolite at very low levels in vivo despite the presence of much higher levels of other endogenous amino acid substrates. For example, neuroactive kynurenate is obtained by transamination of kynurenine. Two aminotransferases have been extensively studied as contributing to the formation of kynureinate from kynurenine in vivo, namely KAT I and KAT II. As noted above, KAT I is identical to GTK. KAT II is identical to glutamate – α-amino adipate aminotransferase (for a review of the role of KATs in the brain see [48]). The concentration of kynurenine and its transamination product kynuremate in the brain are in the 400 nM range and 1 nM range, respectively [48,49]. Thus, kynurenate can be generated in brain through transamination of kynurenine despite the low levels of precursor kynurenine and high levels of endogenous alternative substrates – e.g. glutamine (KAT I) and glutamate (KAT II). Thus, we suggest that it is entirely possible that Cys-S-Hg-S-Cys and CH3Hg-S-Cys even at mM concentrations could be transaminated in vivo.

Transamination of Cys-S-Hg-S-Cys and CH3Hg-S-Cys are predicted to yield the corresponding mercury-containing α-keto acids. However, it is not clear to what extent these α-keto acids might accumulate in vivo given the large pool of GSH (mM) in most tissues and the potential for Hg–S exchange. If the exchange is relatively slow, then it is possible that the α-keto acids derived from Cys-S-Hg-S-Cys and CH3Hg-S-Cys may contribute to the toxic effects in vivo in individuals exposed to organic mercury via food intake, especially since GTK is of relatively high specific activity in the kidney [23], and the kidney is a major site of accumulation of Cys-S-Hg-S-Cys and CH3Hg-S-Cys [13]. It is possible that the α-keto acid analogues of Cys-S-Hg-S-Cys and CH3Hg-S-Cys are produced in vivo they may react with/inhibit α-keto acid-utilizing enzymes thereby contributing to the toxicity. However, the predicted mercury-containing α-keto acids have not yet been characterized and their biological and toxicological properties must await further studies. Finally, if there is some Hg–S exchange between GSH and the α-keto acid analogues of Cys-S-Hg-S-Cys and CH3Hg-S-Cys, mercaptopropionate may be one of the products formed. Mercaptopropionate is a donor of sulfane sulfur to a suitable acceptor in a reaction catalyzed by mercaptopropionate sulfurransferase [50]. Addition of sulfane sulfur to cysteine residues has the potential to modify protein structure and function [50].

In addition, our data show that Cys-S-Hg-S-Cys and CH3Hg-S-Cys (and the corresponding Hcy conjugates) are strongly inhibitory relative to the substrate phenylalanine. However, the exact kinetic mechanism remains to be elucidated. One possibility is that the mercury S-conjugates react covalently (participate in Hg–S exchange) with one or more cysteine residues in rhGTK. Reaction with the cysteine moiety (C127) near the active site (or possibly with more distant cysteines) may account for the apparent noncompetitive type of inhibition observed during our kinetic studies. Planned X-ray crystallographic studies of rhGTK crystallized in the presence of either HgCl2 or Cys-S-Hg-S-Cys should provide additional information.

It is important to note that the activity of many enzymes, including, for example, certain aminotransferases [51,52] and dehydrogenases [53,54], contain cysteine residues that, when modified, can significantly alter enzyme activity. Thiol/disulfide bonds are critical for maintaining the structural, catalytic and allosteric integrity of a vast number of enzymes and signal proteins. In addition, they are key components involved in the maintenance of redox balance and redox-sensitive reaction pathways, and in mediating protein signaling events [21,22,55–57]. Binding of mercury compounds to sulfhydryl centers of exposed cysteine residues may lead to reversible and/or irreversible inhibition of the enzyme, enzyme denaturation and/or protein aggregation. For example, a recent study provides data suggesting that HgCl2 and CH3HgCl irreversibly inhibit the activity of arylamine N-acetyltransferase-1, an intracellular enzyme involved in the biotransformation of aromatic and heterocyclic amines [58]. Similarly, the current study indicates that HgCl2 and CH3HgCl are able to inhibit the intracellular enzymes, GTK and, much more potently and irreversibly, cystathionine γ-lyase. In previous work it was shown that after inactivation of crystalline rat liver cystathionine γ-lyase by p-chloromercuribenzoate, activity could only be partially restored by addition of 2,3-dimercaptopropionate [36].

Although more detailed studies are required to firmly establish the mechanism, the present findings of inhibition of rhGTK by HgCl2 and CH3HgCl have the characteristics of a slow, but reversible noncompetitive inhibition. There is a good precedent for such an occurrence. Frasco et al. [59] showed that human butyrylcholinesterase, which does not possess a cysteine residue sensitive to thiol reagents, is slowly, but reversibly, inhibited (minutes) by mM amounts of HgCl2 in a noncompetitive manner. Human butyrylcholinesterase crystallized in the presence of HgCl2 was found to contain two Hg binding sites with variable Hg occupancy. No Hg was found in the active site or was bound to cysteine sulfur [59]. As noted above, the crystal structure of rhGTK is known [28]. Subsequent studies from our group will focus on rhGTK crystallized in the presence of HgCl2 and mercury S-conjugates. As also noted above, mM concentrations of CH3HgCl and HgCl2 are not biologically relevant. Nevertheless, the results are helpful because they indicate that the compounds will be useful in X-ray crystallographic studies of rhGTK. Moreover, they highlight the different susceptibilities of rhGTK and cystathionine γ-lyase to mercury-containing compounds as discussed below.

HgCl2, Cys-S-Hg-S-Cys and CH3HgCl strongly inhibit cystathionine γ-lyase at μM, or lower, concentrations (Fig. 8). This inhibition is irreversible for HgCl2 and Cys-S-Hg-S-Cys (and probably also for CH3Hg-S-Cys). These findings are markedly different from those noted for rhGTK, where strong inhibition by HgCl2 and CH3HgCl requires mM concentrations. Moreover, inhibition of rhGTK by HgCl2 was shown to be reversible by addition of DTT. [The reversibility of the inhibition by CH3HgCl was not investigated.] As noted above, the sensitivity of cystathionine γ-lyase to inhibition by HgCl2 is probably due to a reactive cysteine in the vicinity of the active site. Again, there is a good precedent in the work of Frasco et al. [59]. These authors showed that, unlike human butyrylcholinesterase, Torpedo californica acetylcholinesterase possesses a cysteine residue sensitive to sulfhydryl reagents, and is irreversibly inhibited in a pseudo-first-order process by μM amounts of HgCl2.

The earlier discovery that mercury species bond avidly with thiol-containing biomolecules to form S-conjugates such as Cys-S-Hg-S-Cys and CH3Hg-S-Cys [9] was instrumental in expanding our understanding of the toxicity of mercury compounds within target organs and cells. When these S-conjugates of mercury act as molecular analogues of endogenous, sulfur-containing amino acids, they broaden the scope of the toxicological consequences of mercury exposure. Indeed, the present study shows that Cys-S-Hg-S-Cys is a potent irreversible inhibitor of cystathionine γ-lyase, while both Cys-S-Hg-S-Cys and CH3Hg-S-Cys are aminotransferase substrates and reversible inhibitors of GTK. In rodents, the specific activity of cystathionine γ-lyase is highest in the liver followed by kidney, with much lower...
levels in other organs [60]. On the other hand, the specific activity of GTK is highest in kidney, but the enzyme is also notably active in liver and, to a lesser extent, in brain and other organs [22,24]. Thus, the differences in organ toxicity of Cys-S-Hg-S-Cys versus CH3Hg-S-Cys may be related, in part, to differences in the way the compounds interact with enzymes/transporters. For example, CH3Hg-S-Cys, but not Cys-S-Hg-S-Cys, has been shown to cross the blood–brain barrier via the amino acid transporter, system L [61,62]. Given that the human brain contains large amounts of cystathionine [63], the neurotoxicity of CH3Hg-S-Cys may be related, in part, to its transport through the blood–brain barrier and its subsequent targeting of cystathionine metabolism/turover/function in the human brain. These mercury-containing organosulfur conjugates are the forms to which humans would be most often likely exposed following consumption of contaminated fish that are high in the food chain. Thus, the metabolic burden of processing inorganic or organic forms of mercury, such as monomethyl S-conjugates, would be expected to occur within tissues of autotrophic species and/or animals lower in the food web that are initially exposed to mercury from the atmosphere or that settled in water.

Clearly human exposure to mercury-containing compounds has numerous consequences, not only at the organ level, but also at the cellular/molecular level. Our results emphasize the fact that mercury not only binds covalently and indiscriminately to thiol moieties in proteins, but once conjugated with sulfur-containing amino acids, not only binds covalently and indiscriminately to thiol moieties in cellular/molecular level. Our results emphasize the fact that mercury
