ABSTRACT

Progressive loss of functioning nephrons, secondary to age-related glomerular disease, can impair the ability of the kidneys to effectively clear metabolic wastes and toxicants from blood. Additionally, as renal mass is diminished, cellular hypertrophy occurs in functional nephrons that remain. We hypothesize that these nephrons are exposed to greater levels of nephrotoxicants, such as inorganic mercury (Hg2+), and thus are at an increased risk of becoming intoxicated by these compounds. The purpose of the present study was to characterize the effects of aging on the disposition and renal toxicity of Hg2+ in young adult and aged Wistar rats. Paired groups of animals were injected (i.v.) with either a 0.5 μmol·kg−1 non-nephrotoxic or a 2.5 μmol·kg−1 nephrotoxic dose of mercuric chloride (HgCl2). Plasma creatinine and renal biomarkers of proximal tubular injury were greater in both groups of aged rats than in the corresponding groups of young adult rats. Histologically, evidence of glomerular sclerosis, tubular atrophy, interstitial inflammation and fibrosis were significant features of kidneys from aged animals. In addition, proximal tubular necrosis, especially along the straight segments in the inner cortex and outer stripe of the outer medulla was a prominent feature in the renal sections from both aged and young rats treated with the nephrotoxic dose of HgCl2. Our findings indicate 1) that overall renal function is significantly impaired in aged rats, resulting in chronic renal insufficiency and 2) the disposition of HgCl2 in aging rats is significantly altered compared to that of young rats.

1. Introduction

Aging often leads to significant structural and physiological changes in the kidneys, with the glomerulus being the primary target of the aging process. Age-related glomerular changes are characterized by thickened glomerular basement membranes, expanded mesangial matrices, shrinkage and occlusion of the glomerular capillaries, and eventual glomerulosclerosis (Choudhury et al., 2004; Lopez-Novoa, 2008; Zhou et al., 2008a, 2008b). These changes ultimately lead to atrophy and death of nephrons associated with diseased glomeruli. As the number of functional nephrons decreases, vascular, glomerular, and tubular changes occur in the remaining functional nephrons in an attempt to compensate for the reduction in renal function caused by the diseased nephrons (Lopez-Novoa, 2008; Zatz and Fujihara, 1994). These compensatory changes result in glomerular hypertrophy, hyperperfusion, and hyperfiltration and lead to increases in single nephron glomerular filtration rates (SNGFR) and intraglomerular shearing forces, which predispose the affected glomeruli to sclerotic changes (Anderson and Brenner, 1986; Fogo, 2000; Lopez-Novoa, 2008; Weinstein and Anderson, 2010). Indeed, a positive correlation between glomerular hypertrophy and the development of glomerulosclerosis has been demonstrated in aging mice (Feder et al., 1994). In addition, the proliferation of mesangial cells and expansion of the mesangial matrix, both of which may be frequently associated with glomerular hypertrophy, appear to precede and contribute to the development of glomerulosclerosis (Floge et al., 1992). Age-related changes have also been observed in epithelial cells of renal tubules and the interstitium. These changes include atrophy and degeneration, formation of diverticula, irregular thickening of the tubular basal lamina and tubulointerstitial fibrosis, which can be associated with interstitial inflammation, fibroblast activation, increased deposition of collagen, and nephrocalcinosis (Abrass et al., 1995; Ding et al., 2001; Thomas et al., 1998; Zhou et al., 2008a, 2008b). It should be noted that these changes are considered to be pathological and they are distinctly different from the compensatory changes that occur following the loss of renal mass that occurs with uninephrectomy (Hayslett et al., 1968).

As the number of functioning nephrons diminishes in aged kidneys, the remaining functional nephrons undergo compensatory changes in order to maintain normal renal function (Fine and Norman, 1989; Fine et al., 1992). These changes may consequently lead to increased exposure of renal tubular epithelial cells to metabolic wastes and xenobiotics, including nephrotoxicants. In addition, these substances may be taken up more readily by hypertrophied and hypermetabolic proximal tubular cells because of compensatory increases in blood flow within.

glomeruli and expression of certain cellular transport mechanisms along the proximal tubule. The increased exposure to, and probable increase in uptake of available nephrotoxics likely enhances the risk of hypertrophied tubular cells being affected adversely by these substances (Lopez-Novoa, 2008). These adverse effects could conceivably lead to additional cell death along the nephron and possibly additional glomerulosclerosis, both of which would further reduce functional renal mass.

Mercury is a nephrotoxic metal that is found ubiquitously in many environmental and certain occupational settings. Most often, humans are exposed to organic forms of mercury such as methymercury (CH₃Hg⁺) through consumption of contaminated fish. Once ingested, a fraction of CH₃Hg⁺ is oxidized to form inorganic mercury (Hg²⁺). Although both forms of mercury have been shown to accumulate in the kidney, this organ appears to be a preferential site of Hg²⁺ accumulation. Indeed, renal accumulation of Hg²⁺ occurs rapidly with as much as 40% as Hg²⁺ may enhance morbidity and even mortality. Owing to the prev

2. Methods

2.1. Animals

Male Wistar rats were obtained from our breeding colony housed in the Mercer University School of Medicine animal facility. “Young” rats were used at an age of eight weeks while “Aged” rats were approximately 20 months of age. Mean body weights for each group of animals are listed in Table 1. Each kidney was trimmed of fat and fascia and total renal mass and liver weights for each group of animals are

*Significantly different (p < 0.05) from mean of group of young rats exposed to the same dose of HgCl₂.

Animals were handled in accordance with the Guide for the Care and Use of Laboratory Animals as adopted by the National Institutes of Health.

2.2. Intravenous injections

Rats were injected intravenously (i.v.) with either a non-nephrotoxic (0.5 μmol · kg⁻¹ · 2.0 mL⁻¹ normal saline) or a nephrotoxic (2.5 μmol · kg⁻¹ · 2.0 mL⁻¹ normal saline) dose of HgCl₂ according to our previously published protocol (Bridges et al., 2008a, 2008b). The injection solution contained radioactive mercury ([²⁰³Hg²⁺]) and was designed to deliver 1 μCi [²⁰³Hg²⁺] to each animal. [²⁰³Hg²⁺] was generated by neutron activation of mercuric oxide for four weeks at the University of Missouri Research Reactor (MURR) (Belanger et al., 2001; Bridges et al., 2008a). At the time of injection, each animal was anesthetized with isoflurane and a small incision was made in the skin in the mid-ventral region of the thigh to expose the femoral vein and artery. A 0.5 μmol or 2.5 μmol · kg⁻¹ dose of HgCl₂ was administered into the vein. The wound was closed using two 9-mm stainless steel wound clips. Animals were then housed individually in metabolic cages. Forty-eight hours after injection with HgCl₂, animals were sacrificed and organs/tissues were harvested.

2.3. Collection of organs

At the time of euthanasia, animals were anesthetized with ketamine (70 mg · kg⁻¹) and xylazine (30 mg · kg⁻¹). A 1-mL sample of blood was obtained from the inferior vena cava and set aside for the determination of [²⁰³Hg²⁺] content. A separate sample of blood was placed in a Microtainer plasma separation tube in order to estimate the content of [²⁰³Hg²⁺] in plasma and cellular fractions. The total volume of blood was estimated to be 6% of body weight (Lee and Blaufuss, 1985).

The liver and kidneys were also removed from each rat. The mean total renal mass and liver weights for each group of animals are shown in Table 1. Each kidney was trimmed of fat and fascia and weighed and cut in half along the mid-traverse plane. One-half of the right kidney was placed in fixative (40% formaldehyde, 50% glutaraldehyde in 96.7 mM NaH₂PO₄ and 67.5 mM NaOH) as preparation for histological analyses. The remaining half was frozen in liquid nitrogen for future RNA analyses. One-half of the left kidney was utilized for estimation of [²⁰³Hg²⁺] content. A 3-mm traverse slice was obtained from the remaining half and was used for dissection of renal zones (cortex, outer stripe of the outer medulla, inner stripe of the outer medulla, and inner medulla). Each sample was weighed and placed in a separate tube for estimation of [²⁰³Hg²⁺]. The liver was weighed and a 1-g sample was removed for determination of [²⁰³Hg²⁺] content.

Urine and feces were collected in 24-h periods throughout the duration of the experiment. Urine volumes are listed in Table 2. At the end of each 24-h collection period, a 1-mL sample of urine was weighed and placed in a tube for estimation of [²⁰³Hg²⁺] content. All of the feces excreted during each 24-h collection period were counted for estimation of [²⁰³Hg²⁺] content. The content of [²⁰³Hg²⁺] in each sample was determined by counting in a Wallac Wizard 3 Automatic Gamma Counter (Perkin Elmer, Boston, MA) and the content of Hg²⁺ in each sample was estimated using standard computational methods.

2.4. Real-time PCR

Kidneys from young and old Wistar rats injected with 0.5 μmol or 2.5 μmol HgCl₂ · kg⁻¹ were isolated, cut into sections, and frozen at the time of animal sacrifice. At the time of RNA isolation, frozen kidney sections were pulverized with a mortar and pestle. TRIzol Reagent (Life Technologies, Grand Island, NY) was added to the ground kidney and RNA was extracted according to the manufacturer’s protocol.

Reverse transcription of 1 μg of RNA was carried out using reverse transcriptase and random hexamers (Life Technologies). For real-time
PCR analyses, 2 μL of the reverse transcriptase reaction was utilized. Analysis of kidney injury molecule–1 (Kim–1) and neutrophil gelatinase-associated lipocalin (Ngal) was performed with an ABI Prism 7000 Detection System using a Gene Expression Assay (Rn00597701_m1 and Rn00590612_m1, respectively, Life Technologies). Glyceraldehyde 3-phosphate dehydrogenase (Gapdh; Rn01775763_g1) was used as a reference gene.

2.5. Histology

Kidneys were fixed in 40% formaldehyde, 50% glutaraldehyde in 96.7 mM NaH2PO4 and 67.5 mM NaOH for 48 h at 4 °C. Following fixation, kidneys were washed twice with normal saline and placed in 70% ethanol. Tissues were processed in a Tissue-Tek VIP processor using the following sequence: 95% ethanol for 30 min (twice); 100% xylene (twice). Tissue was subsequently embedded in POLY/Fin paraffin and 5 μm sections were cut using a Leitz 1512 microtome and mounted on glass slides. Sections were stained with hematoxylin and eosin (H & E) and were viewed using an Olympus IX70 microscope. Images were captured with a Jenoptix Progress C12 digital camera.

2.6. Measurement of glucose, protein, creatinine and blood urea nitrogen

Urine samples were frozen for determination of urinary glucose and protein. For analyses of urinary glucose, 5 μL of urine were used and glucose was quantitated using the QuantiChrome glucose assay kit (BioAssay, Hayward, CA). For analyses of urinary protein, 20 μL of urine was added to 1 mL Bradford’s Reagent (Sigma, St. Louis, MO) and absorbance was read at 460 nm. Protein concentrations were calculated from a standard curve.

Plasma creatinine and blood urea nitrogen (BUN) levels were assessed in order to estimate the alterations in renal function. Following separation of plasma from cellular components of blood, samples were stored at −20 °C. For determination of plasma creatinine, 30 μL of plasma was utilized and the concentration of creatinine was assessed using the QuantiChrome creatinine assay (BioAssay). Similarly, using a 5 μL sample of plasma, the concentration of BUN was determined using the QuantiChrome Urea Assay (BioAssay).

2.7. Statistical analyses

Data for each experiment were analyzed first with the Kolmogorov–Smirnov test for normality and then with Leveni’s test for homogeneity of variances. Data were then analyzed using a two-way analysis of variance (ANOVA) to assess differences among the means. When statistically significant F-values were obtained with ANOVA, the data were analyzed using Tukey’s post hoc multiple comparison test. A p-value of ≤ 0.05 was considered statistically significant. Each group of animals contained four rats.

3. Results

3.1. Disposition of mercuric ions in total renal mass

Fig. 1 A shows the renal burden of Hg2+ (% administered dose) in young and old rats following a 48-h exposure to either 0.5 μmol or 2.5 μmol HgCl2 ⋅ kg−1. In rats exposed to 0.5 μmol HgCl2, the renal burden of Hg2+ (% administered dose) was significantly greater in older rats than in younger rats. Following exposure to 2.5 μmol HgCl2 ⋅ kg−1, the renal burden of mercury, in both young and aged rats, was significantly lower than that in rats of corresponding age exposed to 0.5 μmol HgCl2 ⋅ kg−1. The absolute amount of Hg2+ (nmol/g tissue) in the total renal mass is shown in Table 2.

Fig. 1B shows the amount of mercury (% administered dose/g tissue) in kidneys from young and old rats following a 48-h exposure to either

0.5 μmol or 2.5 μmol HgCl₂ · kg⁻¹. The amount of Hg²⁺ in kidneys of young rats exposed to 0.5 μmol HgCl₂ · kg⁻¹ was significantly greater than that of aged rats exposed to the same dose of HgCl₂. Similarly, the amount of Hg²⁺ in kidneys of young rats exposed to the 2.5 μmol · kg⁻¹ dose of HgCl₂ was greater than that of kidneys of aged rats exposed to the same dose of HgCl₂. The amount of Hg²⁺ in kidneys of both young and aged rats exposed to 2.5 μmol HgCl₂ · kg⁻¹ was significantly less than that of corresponding rats exposed to 0.5 μmol HgCl₂ · kg⁻¹.

The disposition of Hg²⁺ in the renal cortex and the outer stripe of the outer medulla (OSOM) was examined because segments of the proximal tubule, which is the primary site of Hg²⁺ accumulation and intoxication, are located within these two zones of the kidney. Fig. 2A shows the amount of Hg²⁺ in the renal cortex (% administered dose/g tissue) 48 h after exposure to 0.5 μmol or 2.5 μmol HgCl₂ · kg⁻¹. When rats were treated with 2.5 μmol HgCl₂ · kg⁻¹, the cortical burden of Hg²⁺ in aged rats was significantly lower than that in younger rats. The amount of Hg²⁺ in the cortex of both young and old rats, exposed to 2.5 μmol HgCl₂ · kg⁻¹ was significantly less than that in the cortex of corresponding rats exposed to 0.5 μmol HgCl₂ · kg⁻¹.

Fig. 2B shows the burden of Hg²⁺ (% administered dose/g tissue) in the OSOM. In rats exposed to 0.5 μmol HgCl₂ · kg⁻¹, the amount of Hg²⁺ per gram of OSOM was greater in young rats than in aged rats. The amount of Hg²⁺ in the OSOM of young and aged rats exposed to 2.5 μmol HgCl₂ · kg⁻¹ was significantly lower than that of corresponding rats exposed to 0.5 μmol HgCl₂ · kg⁻¹. The amount of Hg²⁺ in either the inner stripe of the outer medulla or the inner medulla was very low and was significantly less than that in either the cortex or the OSOM (data not shown). This finding was observed in all groups of rats. The absolute amount of Hg²⁺ (nmol/g) in the cortex and the OSOM is shown in Table 2.

3.2. Disposition of mercuric ions in liver and blood

Fig. 3A shows that approximately 5% of the administered dose of Hg²⁺ was present in the liver of young and aged rats 48 h after exposure to the 0.5 μmol · kg⁻¹ dose of HgCl₂. Following exposure to 2.5 μmol HgCl₂ · kg⁻¹, the hepatic burden of Hg²⁺ was significantly greater in aged rats than that in younger rats (7% administered dose).

Fig. 3B shows the hematologic burden of Hg²⁺ in young and aged rats 48 h following exposure to 0.5 μmol or 2.5 μmol HgCl₂ · kg⁻¹. When rats were exposed to 2.5 μmol HgCl₂ · kg⁻¹, the hematologic burden of Hg²⁺ was significantly greater in young rats than in corresponding aged rats. The hematologic burden of Hg²⁺ in young rats exposed to 2.5 μmol HgCl₂ · kg⁻¹ was significantly greater than that in corresponding young rats exposed to 0.5 μmol HgCl₂ · kg⁻¹. The absolute amount of Hg²⁺ (nmol/g) in the liver and blood is shown in Table 2.

3.3. Elimination of mercuric ions in urine and feces

Fig. 4A shows the total amount of Hg²⁺ excreted in the urine of young and old rats during a 48-h exposure to 0.5 μmol or 2.5 μmol HgCl₂ · kg⁻¹. There were no significant differences in urinary excretion of Hg²⁺ between young and aged rats at either dose of HgCl₂. However, the urinary elimination of Hg²⁺ in young and aged animals was significantly greater following exposure to 2.5 μmol HgCl₂ · kg⁻¹ than that after exposure to 0.5 μmol HgCl₂ · kg⁻¹. The absolute amount of Hg²⁺ (nmol/g tissue/mL urine) excreted in urine is shown in Table 2.
Fig. 4B shows the cumulative fecal excretion of Hg\(^{2+}\) in young and aged rats during the initial 48 h following exposure to 0.5 \(\mu\)mol or 2.5 \(\mu\)mol HgCl\(_2\) · kg\(^{-1}\). In rats exposed to 0.5 \(\mu\)mol HgCl\(_2\), the fecal excretion of Hg\(^{2+}\) was significantly greater in young rats than in old rats. Similarly, in rats exposed to 2.5 \(\mu\)mol HgCl\(_2\) · kg\(^{-1}\), the fecal excretion of Hg\(^{2+}\) was also significantly greater in young rats than in aged rats. The absolute amount of Hg\(^{2+}\) (nmol) eliminated in feces is shown in Table 2.

3.4. Biochemical analyses of renal function

There were significant differences in the total amount of glucose excreted in urine (per 48 h) of young and aged rats (Table 3). The total amount of glucose (mg/48 h) excreted in urine of young rats exposed to 0.5 \(\mu\)mol HgCl\(_2\) · kg\(^{-1}\) was significantly greater than that excreted in urine of aged rats exposed to the same dose of HgCl\(_2\). Similarly, the total amount of glucose excreted in urine of young rats exposed to a 2.5 \(\mu\)mol · kg\(^{-1}\) dose of HgCl\(_2\) was significantly greater than that excreted in urine of aged rats exposed to the same dose of HgCl\(_2\). When the urinary excretion of glucose by rats exposed to a non-nephrotoxic dose of HgCl\(_2\) (0.5 \(\mu\)mol · kg\(^{-1}\)) was compared to that of rats exposed to a nephrotoxic dose of HgCl\(_2\) (2.5 \(\mu\)mol · kg\(^{-1}\)), we found that the total urinary excretion of glucose increased significantly in both young and aged rats. The amount of glucose excreted in urine of young rats exposed to 2.5 \(\mu\)mol HgCl\(_2\) · kg\(^{-1}\) was approximately six-fold greater and significantly different than that of young rats exposed to the non-nephrotoxic dose of HgCl\(_2\) (0.5 \(\mu\)mol · kg\(^{-1}\)). Similarly, in aged rats exposed to 2.5 \(\mu\)mol HgCl\(_2\) · kg\(^{-1}\), the total amount of glucose excreted in urine was approximately three-fold greater and significantly different than that excreted in urine of aged rats exposed to 0.5 \(\mu\)mol HgCl\(_2\) · kg\(^{-1}\).

When the total amount of protein excreted in urine following a 48-h exposure to HgCl\(_2\) was measured, we found significant differences between young and aged rats (Table 3). The total urinary excretion of protein (per 48 h) in aged rats exposed to 0.5 \(\mu\)mol HgCl\(_2\) · kg\(^{-1}\) was significantly greater than that excreted by young rats exposed to the same dose of HgCl\(_2\). Similarly, in aged rats exposed to 2.5 \(\mu\)mol HgCl\(_2\) · kg\(^{-1}\), the total amount of protein excreted in urine of aged rats was significantly greater than that excreted in urine of corresponding young rats exposed to the same dose of HgCl\(_2\). Furthermore, exposure to a nephrotoxic dose of HgCl\(_2\) (2.5 \(\mu\)mol · kg\(^{-1}\)) led to significant increases in the total amount of protein excreted in urine of young rats exposed to a non-nephrotoxic dose of HgCl\(_2\).

BUN was measured as a means to estimate the retention of nitrogen by-products of intermediary metabolism and consequently, renal function (Table 4). The levels of BUN in control rats were similar to those of rats exposed to 0.5 \(\mu\)mol HgCl\(_2\) · kg\(^{-1}\). In rats exposed to 0.5 \(\mu\)mol HgCl\(_2\) · kg\(^{-1}\), BUN was significantly greater in aged rats than in corresponding young rats. In contrast, following exposure to 2.5 \(\mu\)mol HgCl\(_2\) · kg\(^{-1}\), no significant differences were noted between young and aged rats. As expected, BUN was significantly greater in rats (young and aged) exposed to 2.5 \(\mu\)mol HgCl\(_2\) · kg\(^{-1}\) than in rats exposed to 0.5 \(\mu\)mol HgCl\(_2\) · kg\(^{-1}\).

3.5. Real-time PCR analyses of renal biomarkers

Real-time PCR was utilized to analyze renal expression of kidney injury molecule-1 (Kim-1) and neutrophil gelatinase associated lipocalin (Ngal) in the kidneys of young and aged rats exposed to saline (control), 0.5 \(\mu\)mol HgCl\(_2\) · kg\(^{-1}\) or 2.5 \(\mu\)mol HgCl\(_2\) · kg\(^{-1}\) (Fig. 5). Kim-1, which is also known as hepatitis A virus cellular receptor 1 (Havcr1) is a transmembrane protein that is expressed at high levels in proximal tubular epithelial cells following ischemic or toxic injury (Ichimura et al., 2004).

\(^a\) Significantly different (\(p < 0.05\)) from mean of group of young rats exposed to same dose of HgCl\(_2\).

\(^b\) Significantly different (\(p < 0.05\)) from mean of group of rats of the same age exposed to 0.5 \(\mu\)mol HgCl\(_2\) · kg\(^{-1}\).

\(^c\) Significantly different (\(p < 0.05\)) from mean of 24 h volume.
The expression of Kim-1 mRNA in control rats was similar between young and aged rats (Fig. 5A). In contrast, Kim-1 expression was significantly greater in aged rats than in corresponding young rats exposed to 0.5 μmol · kg⁻¹. Exposure of rats to a nephrotoxic dose of HgCl₂ (2.5 μmol · kg⁻¹) led to a dramatic increase in the mRNA expression of Kim-1 in both young and aged rats, compared to corresponding control rats or rats exposed to 0.5 μmol HgCl₂ · kg⁻¹.

Ngal is a small polypeptide that is secreted by injured proximal tubular cells and has been shown to be a marker for renal injury (Mishra et al., 2003; Supavekin et al., 2003). The expression of Ngal mRNA was significantly greater in aged rats exposed to either dose of HgCl₂ than in corresponding young rats or control rats (Fig. 5B). Moreover, mRNA expression of Ngal in rats (young and aged) exposed to 2.5 μmol HgCl₂ · kg⁻¹ was significantly greater than that in corresponding groups of rats exposed to the 0.5 μmol · kg⁻¹ dose of HgCl₂.

### 3.6. Histological analyses of renal structure

Fig. 6 shows the photomicrographic images of hematoxylin and eosin (H & E) stained sections of kidneys removed from young and aged Wistar rats exposed to 0.5 μmol or 2.5 μmol HgCl₂ · kg⁻¹. Panels A and B show the representative photomicrographs of renal sections from young rats exposed to 0.5 μmol HgCl₂ · kg⁻¹. Panel A demonstrates normal cortical tissue while Panel B shows normal tissue from the outer stripe of the outer medulla (OSOM). The inner stripe of the outer medulla and the inner medulla were also examined and no evidence of pathological alterations was observed (data not shown). Since the 0.5 μmol · kg⁻¹ dose of HgCl₂ has been shown previously to be non-toxic (Zalups, 1993b), it is assumed that the histological features observed in Panels A and B are similar to that which would be observed in sections of kidneys from rats that have not been exposed to HgCl₂. Indeed, no pathological alterations were observed in any of these sections. Panels C and D are representative photomicrographs of kidneys from young rats exposed to a nephrotoxic dose of HgCl₂ (2.5 μmol · kg⁻¹). The major histopathological finding was the significant necrosis along

* Significantly different (p < 0.05) from mean of group of young rats exposed to same dose of HgCl₂.

**Fig. 5.** Real-time PCR analyses of kidney injury molecule-1 (Kim-1) and neutrophil gelatinase associated lipocalin (Ngal). RNA was extracted from kidneys removed from young and aged rats 48 h after intravenous exposure to 0.5 μmol or 2.5 μmol HgCl₂ · kg⁻¹. Each value represents a mean ± SE for twelve samples from four rats. *Significantly different (p < 0.05) from the mean of young rats exposed to the same dose. + Significantly different (p < 0.05) from the mean of corresponding rats exposed to 0.5 μmol HgCl₂.

**Fig. 6.** Photomicrographs of histological sections of kidneys removed from young and aged rats 48 h after intravenous exposure to 0.5 μmol or 2.5 μmol HgCl₂ · kg⁻¹. Sections were stained with H & E. Arrows indicate glomeruli, arrowheads indicate cellular necrosis, and asterisks denote proteinaceous casts. A, cortex from young rats exposed to 0.5 μmol HgCl₂ · kg⁻¹; B, outer stripe of outer medulla from young rats exposed to 0.5 μmol HgCl₂ · kg⁻¹; C, cortex from young rats exposed to 2.5 μmol HgCl₂ · kg⁻¹; D, outer stripe of outer medulla from young rats exposed to 2.5 μmol HgCl₂ · kg⁻¹; E, cortex from aged rats exposed to 0.5 μmol HgCl₂ · kg⁻¹; F, outer stripe of outer medulla from aged rats exposed to 0.5 μmol HgCl₂ · kg⁻¹; G, cortex from aged rats exposed to 2.5 μmol HgCl₂ · kg⁻¹; H, outer stripe of outer medulla from aged rats exposed to 2.5 μmol HgCl₂ · kg⁻¹. Sections are representative samples of tissue obtained from each rat (n = 4/group).
the pars recta of proximal tubules, particularly in the inner cortex and OSOM. Panel C shows representative glomeruli in the cortex. The capillary tuft appears shrunken and compressed with proteinaceous material surrounding it in Bowman’s space. Areas of cellular necrosis (arrowheads) were also observed in the cortex. Panel D shows a section of the OSOM, where extensive areas of cellular necrosis (arrowheads) were observed along the pars recta of proximal tubules. Panels E and F show representative photomicrographs from kidneys obtained from aged rats exposed to a 0.5 μmol·kg⁻¹ dose of HgCl₂. Panel E shows the affected glomeruli with significant thickening of glomerular base- membrane membranes and Bowman’s capsule. Glomerular changes were consistent with glomerulosclerosis and were characterized by thickening of the glomerular basement membranes and Bowman’s capsule. Interestingly, some glomeruli were surrounded by a tubular-like, columnar epithelium. Tubular alterations included dilation of tubular lumina, presence of proteinaceous casts within lumina, tubular atrophy and the formation of vacuoles within tubular epithelial cells. In some areas, interstitial infiltration of lymphocytes (interstitial nephritis) was observed. Panel F shows a section of the OSOM with atrophied tubules and proteinaceous casts (asterisks). Panels G and H show representative photomicrographs from sections of kidney removed from aged rats exposed to 2.5 μmol·kg⁻¹ dose of HgCl₂. Panel G shows sclerotic glomeruli (arrows) and necrotic tissue (arrowheads). Panel H shows a section of the OSOM following exposure to a toxic dose of HgCl₂. Tubular necrosis (arrowheads) was induced along the pars recta of proximal tubules in the inner cortex as well as throughout the OSOM. Proteinaceous casts (asterisks) were also identified within lumina of tubules. Although Hg²⁺-induced necrosis was observed in kidneys of aged rats exposed to 2.5 μmol·kg⁻¹, the severity was less than that in corresponding young rats exposed to the same dose.

4. Discussion

Renal function declines significantly with age and has been shown to be related directly to pathological changes in the kidney (Choudhury et al., 2004; Macias-Nunez and Lopez-Novoa, 2008; Shock et al., 1984). Since humans and other mammals possess significant renal functional reserve, the capacity to maintain proper fluid and solute (including electrolyte) balance is generally not compromised in an aging individual even though overall glomerular filtration rate (GFR) may be lower than normal (Bohler et al., 1993; Esposito et al., 2007; Fiser et al., 1993). However, when challenged, such as following exposure to a nephrotoxicant like inorganic mercury (Hg²⁺), the renal functional reserve of an individual may become depleted and lead to additional reductions in filtration capacity and/or substantial alterations in fluid and electrolyte homeostasis (Barai et al., 2010; Uriu et al., 2000). Indeed, it has been suggested that long-term exposure to nephrotoxic heavy metals such as cadmium may exacerbate the effects of age-related decline in GFR (Gonick, 2008; Lauwerys et al., 1992).

In the current study, we examined the disposition and toxicity of Hg²⁺ in young and aged rats exposed to a non-toxic (0.5 μmol·kg⁻¹) or a nephrotoxic (2.5 μmol·kg⁻¹) dose of HgCl₂. The present study is novel in that it is the first to characterize the disposition and toxic effects of Hg²⁺ in aged animals. We found that mercuric ions accumulate primarily in kidneys of both young and aged rats. When considering the total burden of mercury in each kidney (% administered dose), we found that more mercury was present in kidneys of aged animals. This was not surprising since the kidneys of these older rats were larger than those of the younger animals. When the renal burden of mercury was factored by the weight of the kidney (% administered dose/g), we found that the concentration of Hg²⁺ was significantly lower in aged rats than in young rats. This was the case following treatment with either dose of HgCl₂. This finding may relate to the presence of glomerulosclerosis, interstitial fibrosis and impaired renal plasma flow that are characteristic of aged kidneys (Baylis and Schmidt, 1996; Choudhury et al., 2004; Zhou et al., 2008a, 2008b). It has been suggested that kidneys of aged individuals may be more susceptible to toxicants (Mueller et al., 1998; Uriu et al., 2000). This theory may be true of kidneys that are undergoing the initial steps of age-induced pathological change but it may not be applicable to kidneys that already have significant pathological alterations. We propose that there is a period of increased renal susceptibility in which aged kidneys are more susceptible to intoxication because of compensatory changes that occur within the remaining functioning nephrons. The initial point at which pathological alterations begin to develop in nephrons may represent the beginning of the period where remaining functional nephrons may be more susceptible to injury by tubular nephrotoxins. We postulate that this increase in susceptibility may be related to compensatory changes such as glomerular hyperfiltration and increased peritubular blood flow in functional nephrons. These changes could lead to increased exposure of these nephrons to metabolic wastes and nephrotoxins. As the pathological changes progress and the majority of nephrons become sclerotic, the overall renal plasma flow is decreased and nephrons may become less susceptible to nephrotoxins simply because of the inability of these compounds to gain access to renal tissue. In the current study, it appears that glomerulosclerosis in the aged kidneys has progressed to a point where renal plasma flow is decreased and consequently, exposure to toxicants is reduced. We were unable to assess changes in susceptibility at the single nephron level; however, it is possible that at the level of the individual nephron, the effects of mercury may have been more severe in aged rats than in younger rats.

Biochemical analyses of renal function were carried out in order to assess differences in renal function among groups of rats. In young rats exposed to a non-nephrotoxic dose of HgCl₂, plasma creatinine and BUN levels were similar to normal values reported in the current study (Table 4) and by others (Amini et al., 2012; Moenei et al., 2013; Palm and Lundblad, 2005). Similarly, total urinary excretion of glucose and protein reflected previous reports from normal rats not treated with HgCl₂ (Dai et al., 2012; Gray, 1977; McDermott et al., 1996), which indicates that young rats exposed to a non-nephrotoxic dose of HgCl₂ can serve as controls for other groups. In contrast, plasma creatinine and BUN levels of aged rats exposed to a non-toxic dose of HgCl₂ were found to be elevated. These data support previous reports indicating that glomerular filtration is compromised in aged animals and humans (Corman and Owen, 1993; Shock et al., 1984). Interestingly, the total urinary excretion of glucose was lower in aged animals than in young animals, suggesting that filtration of glucose at the site of the glomerulus may be reduced in aged animals. In contrast, urinary excretion of protein was greater in older rats than in younger rats. This protein may originate from the lumina of atrophied tubules or be due to hyperfiltration of protein and diminished absorption.

We also assessed the biochemical parameters of renal function in young and aged rats exposed to a nephrotoxic dose of HgCl₂. In young rats, plasma creatinine, BUN, and urinary excretion of glucose and protein increased significantly following exposure to a nephrotoxic dose of HgCl₂. These changes are related directly to Hg²⁺-induced renal necrosis and tubular dysfunction, which leads to increased urinary excretion of filtered solutes such as glucose (Barbier et al., 2005). Exposure of aged rats to a nephrotoxic dose of HgCl₂ led to similar increases in the aforementioned biochemical parameters. The magnitude of these changes was less in older animals than in young animals, suggesting that a toxic dose of HgCl₂ had a greater effect on renal tissue of younger animals than that of older animals. To our knowledge, these data represent the first characterization of these biochemical parameters in aged rats exposed to a non-nephrotoxic or nephrotoxic dose of HgCl₂.

Kim-1 and Ngal have been shown to be sensitive markers of renal injury following exposure to a number of nephrotoxins, including heavy metals (Han et al., 2012; Prozialeck and Edwards, 2010; Prozialeck et al., 2007; Singer et al., 2013; Sinha et al., 2013). In control animals (not exposed to HgCl₂), the expression of Kim-1 and Ngal was similar in young and aged animals. Exposure to a non-nephrotoxic
dose of HgCl₂ led to an increase in Kim-1 and Ngal in aged, but not young animals. This finding is most likely due to the significant structural alterations that are associated with aging rather than Hg-related nephrotoxicity. The renal expression of Kim-1 and Ngal also increased dramatically in young and aged rats following exposure to a nephrotoxic dose of HgCl₂. This finding is similar to other studies which have reported increases in Kim-1 and Ngal following exposure to nephrotoxins (Han et al., 2012; Prozialeck and Edwards, 2010; Prozialeck et al., 2007).

Histological analyses were carried out to characterize structural and pathological changes in kidneys of young and aged rats exposed to non-nephrotoxic or nephrotoxic doses of HgCl₂. Kidneys of young rats exposed to a non-nephrotoxic dose of HgCl₂ appeared normal. In kidneys of aged animals exposed to a non-nephrotoxic dose of HgCl₂, we identified widespread glomerulonephrosis, proteinaceous casts, atrophied tubules, and interstitial fibrosis similar to that which has been reported previously (Corman and Owen, 1993; Short and R. S., 1993). When rats were exposed to a nephrotoxic dose of HgCl₂, significant pathological changes were evident in both old and young rats. Similar to previous reports (Zalups and Diamond, 1987), widespread cellular necrosis was found in pars recta segments of proximal tubules located in the OSOM and along medullary rays in the cortex. It should be noted that the proximal tubule has been shown to be the primary target of Hg⁺ accumulation and intoxication (Bridges and Zalups, 2005, 2010; Zalups, 2000). The necrosis was more severe in kidneys of younger rats, which was not surprising considering that the amount of Hg⁺ detected in the kidneys of young and aged rats was significantly greater than that of other rats (at both doses of HgCl₂).

The current study not only provides additional documentation of functional and structural alterations in aged kidneys, but is also the first to describe the disposition of and toxicity related to HgCl₂ administered acutely to aged rats. It has been postulated previously that kidneys of older animals may be more susceptible to the intoxicating effects of nephrotoxic compounds; however, in the current study, the sclerotic state of the kidneys appears to be somewhat protective against nephrotoxins. Additional experiments carried out earlier in the aging process are necessary to fully characterize the susceptibility of aged kidneys to toxicants.

Conflict of interest
The authors have no conflicts to disclose.
