DEDICATION

In loving memory of my dear paw-paw, one of my greatest fans.

Me-maw used to always say we got our brains from you, because she still has hers...

so thanks for that.
ACKNOWLEDGEMENTS

A big thank you to Jake Carpenter, Candice Girod, Professor Harshbarger, and Dr. Laura Lackey for organizing and leading the Mercer on Mission (MOM) 2014 trip to Uganda. This research would not have been possible without you; and many thanks to the MOM team for helping collect water quality data at each borehole: Zoe Becton, Sydney Brogden, Amanda Clark, Caroline Cooper, Ray Gormley, Andrew Hearn, Jasmine Jackson, Blaze Jefferies, James McNichols, Aaron Odom, Tony Schmidt, Hannah Smith, Alec Stewart, Andrew Wohlrabe, Catherine Hawkins, and Dr. Craig McMahan. Thank you also to the women and community members at each borehole for their openness and willingness to answer any questions we had.

I would also like to extend a thank you to my thesis committee: Dr. Lackey for all your patience, guidance, and encouragement during this process. Thank you for challenging me to take the thesis route and believing that I could do it—it was worth it; Dr. Butler for advice on statistical methods to use for analysis of the data; and Dr. MacCarthy for your perspective and practical guidance.

Thank you also to Christie Hutchinson and Andrew Wohlrabe for your comments during our thesis meetings with Dr. Lackey and Dr. MacCarthy. Trena Rogers and Denise Collins—thank you for your formatting and logistics help during this process, and thank you Dr. Rood for allowing me to have access to the ArcGIS
Lastly thank you to my family and friends for supporting me and encouraging me when I needed it. Thank you especially to my family for always encouraging me in my endeavors no matter how far they take me.

ABSTRACT

FIELD STUDY INVESTIGATING THE POTENTIAL OF WATER QUALITY TESTING TO PREDICT CORROSION IN BOREHOLES IN NORTHERN UGANDA

Under the direction of DR. LAURA W. LACKEY

Water sources are often abandoned by communities for two reasons: (1) the aesthetics of water quality that affects user acceptability and (2) the breakdown of pump parts that prohibits use of the borehole. Both can be related to the aggressiveness of water and both are important. Electroconductivity and pH and indices can indicate the potential of galvanic corrosion and electrochemical corrosion, respectively. Electrochemical corrosion contributes most to the high levels of iron from boreholes. The purpose of this study was to investigate the efficacy of pH strips in predicting groundwater pH and aggressiveness, compare the reliability of three different pH test strips to a Hanna pH probe, determine the origin of iron measured in boreholes, and make relevant recommendations.

Qualitative and quantitative data were collected at 16 borehole sites in the Amuru and Gulu Districts of Northern Uganda. Water quality testing measuring pH and iron concentration and two types of pump tests—a pump performance test and a
Water Aid pump test–were performed at specified boreholes. Interviews with members from the community at each borehole were conducted and observational data was collected. The pH was measured in triplicate using three different pH test strips (Youth Waters, MN, and Extended Range) and compared to the pH measured with a Hanna probe. Paired t-tests and the Bland-Altman difference method were used to compare pH test strip and Hanna probe measurements.

Results suggest pH strips are an inexpensive method for reliably measuring the pH. Paired t-tests conducted at $\alpha=0.05$ showed that the Youth Waters pH test strip measurements were significantly different than the Hanna probe measurements. Statistical analysis using paired t-tests and the Bland-Altman difference method suggests that the MN and Extended Range test strips are statistically acceptable replacements for the Hanna probe for measuring pH at boreholes in Northern Uganda. Based on the cost, the ease of use, and the statistical analyses, the use of the MN test strips is highly recommended if they are accessible to the user. Results from pump tests suggest that much of the iron observed in borehole water pump effluent is from corrosion of pump components. Iron concentration, pH of groundwater, and electroconductivity should be considered when constructing or rehabilitating a borehole. Future work should follow the methods outlined in this study, measure additional water quality parameters including dissolved oxygen and ammonium concentrations, and include a detailed analysis of the local supply chain of pH test strips and pipe materials available in Gulu, Uganda.

CHAPTER 1. INTRODUCTION

1.1 The Joint Monitoring Program & Improved Water Supply

The Joint Monitoring Programme (JMP) is an initiative by the World Health Organization (WHO) and the United Nations Children’s Fund (UNICEF) to monitor countries’ access to water supply and sanitation in order to monitor the progress of Millennium Development Goal (MDG) 7, Target 7c, the objective being to “Halve, by 2015, the proportion of people without sustainable access to safe drinking-water and basic sanitation” [1]. For monitoring purposes, a set of standards was established to identify categories within drinking water and sanitation. According to JMP, “An “improved” drinking-water source is one that, by the nature of its construction and when properly used, adequately protects the source from outside contamination, particularly faecal matter” [2]. Figure 1 identifies specific “improved” and “unimproved” sources.

According to the 2014 WHO Progress on Drinking Water & Sanitation update, Uganda has met the MDG target for improved drinking water sources [4]. There has been a 33% increase in access to improved water sources from 1990-2012 in Uganda–42% improved drinking water coverage in 1990 to 75% improved drinking water coverage in 2012. The JMP 2014 Update reported 70% of Uganda’s drinking water sources to be considered “other improved” and 5% to be “piped on premises” (Figure 2) [5]. "Other improved" being improved sources that are not piped systems.
Types of drinking water sources as identified by WHO/UNICEF JMP for Water Supply and Sanitation [2], [3].

**Figure 1.** Types of drinking water sources as identified by WHO/UNICEF JMP for Water Supply and Sanitation [2], [3].

Use of the following sources:
- Piped water into dwelling, yard or plot
- Public tap or standpipe
- Tubewell or borehole
- Protected dug well
- Protected spring
- Rainwater collection

Use of the following sources:
- Unprotected dug well
- Unprotected spring
- Cart with small tank or drum
- Tanker truck
- Surface water (river, dam, lake, pond, stream, canal, irrigation channel)
- Bottled water

**Figure 2.** Urban, rural, and total drinking water trends in Uganda from 1990-2012 [5].
As a part of JMP’s efforts to keep drinking water trend progress per country up to date, the organization maintains a database of surveys conducted by in-country groups. Surveys in Uganda have been documented every 1-3 years since 1989. In 2011 the National Panel Survey estimated 35.1% of Uganda’s drinking water sources were “Tubewell, borehole,” specifically identifying this estimate as “Bore-hole” data [5].

1.2 International Iron Concentration Guidelines for Drinking Water

The World Health Organization has not established any guideline values for iron because it is “not of health concern at levels causing acceptability problems in drinking-water”[6]. In general, users will stop drinking water with higher concentrations of iron because of the change in taste or odor before iron concentrations reach a level of health concern.

Uganda has established a drinking water requirement of 0.2-1 mg/L of iron depending on the classification of the source. The two classes are described as follows:

“Class I potable water available from conventional treatment processes...This water is comparable to current international standards for water quality. This water is to be considered acceptable for lifetime consumption, and is the recommended compliance limit.
Class II (untreated water) potable water available for water consumers through boreholes, protected springs, shallow wells, gravity flow schemes and harvested rain water...This class specifies a water quality range that poses an increasing risk to consumers depending on the concentration of the determinant within the specified range and the possibility of monitoring its quality. It is considered to represent drinking water for consumption for a limited period.”

The treated water (Class I) is held at a higher standard of 0.2 mg/L of iron, while the untreated water (Class II) is set at 1 mg/L of iron [7].

In the United States, the Environmental Protection Agency (EPA) has set National Secondary Drinking Water Regulations. These regulations are non-enforceable guidelines for contaminants that could cause cosmetic or aesthetic issues. The recommended secondary maximum contaminant level of iron in drinking water is 0.3 mg/L [8].

1.3 Effects of Close Access to Water Sources

Living in close proximity to an improved water source can provide many benefits to the community. Basic Access as defined by WHO is within 100-1000 m away or 5-30 minutes collection time [9]. The availability of 20 L of water per person per day is considered "reasonable access" [3], [10].

The infrastructure that exists in northern Uganda is aging and the water quality from the studied pumps—specifically the India Mark II and U-Series
Handpumps— is declining, forcing the community members to either continue using the low quality water or travel further to collect water of satisfactory quality. The Ministry of Water and Environment (MWE) of Uganda stated, “Despite the increase in national access to safe water, women and children in Northern Uganda which has just emerged from civil war and semi-arid districts are still burdened with collecting water from long distances” [11]. Collecting water in these conditions can be burdensome and time consuming.

Living close to water sources can benefit women and children greatly. Instead of spending hours collecting water (Figure 3) women can use that time to work, to further provide for their families. WHO completed a study titled the Evaluation of the Costs and Benefits of Water and Sanitation Improvements at the Global Level. This study estimated, “In developing regions, the return on a US$1 investment was in the range of US$5 to US$28 for intervention 1.” Intervention 1 involved “halving the proportion of people without access to improved water sources” [12]. Water has much potential to build an economy.

Without the burden of spending many hours each day collecting water, children are more likely to attend school. Koolwal and Walle found that “in countries where substantial gender gaps in schooling exist, both boys’ and girls’ enrollments improve with better access to water” [13]. This could also be attributed to the health effects of better access to water. Children who are sick from water-related infections often do not or cannot attend school.
David Bradley defined disease transmission routes related to water infections \((Table 1)\). The transmission of water-washed, water-based, and water-related insect vector infections can be minimized and routes can be interrupted when there is access to improved water sources \[14\].

1.4 Motivation and Research Goals

Much of the borehole infrastructure in northern Uganda is in need of repair or replacement. Water sources are often abandoned by community members for two reasons: (1) the aesthetics of water quality that affects user acceptability and (2) the breakdown of pump parts that prohibits use of the borehole. Both can be related to the aggressiveness of water and both are important.

The WHO recognizes the role acceptability plays in water use habits. For example, as mentioned in Section 1.2, they do not have a guideline for iron concentration in water, because they have observed that people will stop using the water because of aesthetic/acceptability reasons before the concentration of iron in
the water becomes a health concern [6]. Water may give off an odor or may turn a
different color due to high concentrations of different contaminants. This can lead to
the abandonment of a water source and can result in families having to travel
further to collect their daily water (Figure 4).

*Figure 4.* Water color of a sample of water taken from a Northern Uganda borehole
progressively darkened as it was heated to a boil (left to right). The image in the
fourth quadrant shows the state of the water once removed from the fire. The
borehole has been chained up because the community did not deem the water
acceptable for use. Many prefer collecting water from the unprotected spring.
(Photos courtesy of Jake Carpenter)
Families cannot be expected to use the water from boreholes like that shown above for any tasks that require boiling water. The boiled water would certainly stain food, clothing, etc. (*Figure 5*).

*Figure 5. A piece of paper dipped in the water from the fourth quadrant pictured above in *Figure 4*. Photo courtesy of Jake Carpenter.*

Many of the borehole systems have been constructed using galvanized iron (GI) rods for raising/lowering the plunger and galvanized iron riser pipes for conveying the pumped water from a depth to the surface. This material when repeatedly in contact with aggressive water will corrode. Aggressive water is defined as water with qualities (acidic or soft) that are conducive to the corrosion of pipe components. Corrosion of the GI pipes can lead to high concentrations of iron in the water supply and/or to the breakdown of the pump. Both have the potential to lead to the abandonment of the borehole.

Mercer on Mission (MOM) is a five week service-learning program that strives to provide students from Mercer University with opportunities to learn
while serving others in an international context. One of the goals of the MOM-Uganda 2014 trip was to conduct water-related research that would improve the quality of life for some people in Uganda. Water quality data was collected at a number of borehole sites in the surrounding area of Gulu town to further understand the relationship between iron concentration, pH and pump configuration, and address the needs of the local communities and government.

The goals of this research include:

1. To investigate the efficacy of using pH test strips to predict groundwater pH and aggressiveness,
2. To compare the reliability and validity of three different pH test strips to a Hanna pH probe,
3. To determine if the origin of the iron measured in borehole pump effluent is from groundwater geography or from the corrosion of GI material associated with the pump rods and riser pipes, and
4. To provide recommendations to field workers and the district water authorities about parameters to consider during borehole construction and rehabilitation.

The rehabilitation of boreholes throughout this document refers to (1) replacing pump components with appropriate corrosion resistant materials
and/or (2) replacing broken pump parts due to corrosion with corrosion resistant ones.
CHAPTER 2. LITERATURE REVIEW

2.1 Corrosion

Corrosion is an issue in water systems across the world. In 2002 the United
States Federal Highway Administration (FHWA) with the help of CC Technologies
Laboratories, Inc. and the National Association of Corrosion Engineers (NACE)
released a 2-year corrosion study, “Corrosion Costs and Preventative Studies in the
United States.” The study reported, “The total annual direct cost of corrosion for
drinking water and sewer systems is $36 billion, which includes the costs of
replacing aging infrastructure, lost water from unaccounted-for leaks, corrosion
inhibitors, internal mortar linings, external coatings, and cathodic protection.” This
is 75% of the annual corrosion cost for utilities in the U.S. [15].

Uganda estimates 5% of their water sources are piped on premises and 70%
are "other improved" [5]. There is no data available similar to that reported by the
United States. However, the effect of corrosion in water supply sources in Uganda
has been observed [16]. Complaints of high levels of iron in boreholes have caused
the water sector in Uganda to make changes in design to create a corrosion-resistant
handpump option, the U3M [17].
There are several different methods that are useful for predicting if water is corrosive or aggressive. Langenegger recommends using a pH index [18](Table 2) and an electroconductivity index to indicate the potential of electrochemical and galvanic corrosion, respectively. Electrochemical corrosion is what contributes most to the high levels of iron at borehole sites. Galvanic corrosion can contribute to mechanical pump failures and generally occurs where different materials come in contact with each other [19]. These pH and electroconductivity indices are just as effective at estimating the corrosion potential as the more complex Langelier Saturation Index [20].

2.1.1 Iron Corrosion Chemistry

Corrosion can be defined as the gnawing away of a material over time. Iron and steel are found in their natural state as iron ore. In this context, corrosion is simply the oxidation of metal to return to its natural state, its lowest, most stable energy level [19], [21]. The World Health Organization explains corrosion of iron as follows:
“The corrosion of iron is a complex process that involves the oxidation of the metal, normally by dissolved oxygen (DO), ultimately to form a precipitate of iron(III). This leads to the formation of tubercules on the pipe surface. The major water quality factors that determine whether the precipitate forms a protective scale are pH and alkalinity. The concentrations of calcium, chloride and sulfate also influence iron corrosion” [6].

WHO suggests adjusting several water quality parameters in order to control iron corrosion (Table 3) [6].

Equations 1-4, below, are the most basic chemical equations that occur during the electrochemical corrosion of iron. Corrosion is a very complex process and many more reactions are likely to occur. The equations include (1) the oxidation of iron in its solid state to form metallic ions, (2) the reduction of oxygen, and (3) & (4) the formation of iron hydroxides (rust) [19].
Anodic Reaction: \( Fe_{(s)} \rightarrow Fe^{2+} + 2e^- \)  
\[ \text{Equation 1} \]

Cathodic Reaction: \( \frac{1}{2}O_2 + H_2O + 2e^- \rightarrow 2OH^- \)  
\[ \text{Equation 2} \]

Secondary Reactions: \( Fe^{2+} + 2OH^- \rightarrow Fe(OH)_2, \铁(II) - \text{hydroxide} \)  
\[ \text{Equation 3} \]
\[ 2Fe^{2+} + \frac{1}{2}O_2 + 4OH^- \rightarrow 2FeOOH, \text{Iron(III) oxyhydroxide (goethite)} + H_2O \]  
\[ \text{Equation 4} \]

Equation 2 is considered the most important cathodic reaction. When this reaction is dominant, the process is referred to as "oxygen corrosion." The reduction of hydrogen (hydrogen ion to hydrogen), however, is also an important cathodic reaction. When this reaction is dominant the process is referred to as "hydrogen corrosion"[19].

2.1.2 Kuch Mechanism

The Kuch mechanism proposes a pathway for corrosion to continue when dissolved oxygen is depleted. Stagnation occurs overnight in boreholes when they are not in use, resulting in low DO levels. The overall reaction, shown in Equation 5, results in ferrous iron and hydroxide.

Overall Reaction: \( Fe(s) + 2FeOOH(s) + 2H^+ \leftrightarrow 3Fe^{2+} + 4OH^- \)  
\[ \text{Equation 5} \]

Kuch suggests that the cathodic reduction in the scale maintains the anodic oxidation of the iron metal. Once flow continues again in the well, oxygen
concentration increases and the ferrous iron is oxidized. The oxidation of Fe(II)-ions can result in a red effluent [22]-[24].

2.1.3 Iron Related Bacteria

Iron related bacteria (IRB) originate from the soil or from contaminated equipment or parts used during the construction, operation and maintenance of the well. It can be difficult to rid the well of IRB once contaminated. One method used to eliminate the bacteria includes chlorinating the borehole. This, however, does not usually eliminate all of the bacteria, thus chlorination is a temporary fix that may need to be repeated occasionally [25].

Iron "promotes the growth of “iron bacteria”, which derive their energy from the oxidation of ferrous iron to ferric iron [Equations (3) & (4)] and in the process deposit a slimy coating on the piping" [6]. The buildup of this coating is often referred to as iron biofouling [26]. These coatings, usually denoted as biofilms, are a result of microbiological activity of iron bacteria (Figure 6). The presence of ammonium (NH₄⁺) is often an indicator of the presence of iron bacteria, and the ammonium concentration increases as the biofilm develops. Temperatures near 30°C also play a role in promoting microbiological activity [19].
2.1.4 Observations of Corrosion

The RWSN 2013 Hand Pump Survey quotes several organizations in Uganda that have experienced issues with high iron concentrations. In the survey the Government of Uganda and an NGO in Uganda cited complaints of poor color and taste of water due to corrosion [16]. "At levels above 0.3 mg/l, iron stains laundry and plumbing fixtures. There is usually no noticeable taste at iron concentrations
below 0.3 mg/l, although turbidity and colour may develop” [6]. Water with high iron concentrations can also stain foods when cooking.

“The incidence and extent of corrosion damage depends mainly on three factors – pump component materials, groundwater quality, and (often overlooked) the pumping regime” [26]. These three areas will be further discussed in this chapter.

2.2 Appropriate Pump Component Materials

Determining whether water is aggressive can help determine if the borehole or handpump should be constructed with corrosion resistant materials. Certain materials can help prevent breakdowns due to corrosive water. The Uganda National Bureau of Standards (UNBS) provides recommendations on handpump materials to use based on water quality and chemistry (Table 4) [28], [29].

Local communities are responsible for performing maintenance and minor repairs of boreholes and handpumps [30]. If spare parts of certain materials are too expensive or not readily available, maintenance and repair can be delayed. *The Community Water Supply-The Handpump Option* states, “the best corrosion resistance is provided by those using plastic rising mains, stainless steel, brass or plastic cylinders, and stainless steel, wooden, or fiber glass rods” [27].

2.2.1 Galvanized Iron

Galvanized Iron (GI) is typically used when constructing India Mark II handpumps. GI materials, however, cannot be recommended where the pH of groundwater is less than 6.5 [18]. Given time, GI will corrode under these conditions.

2.2.2 Stainless Steel

Langenegger states that, “As a general rule...stainless steel rising mains and rods are about 3-5 times more expensive than galvanized ones” [18]. In terms of capital cost, stainless steel (SS) is the most expensive corrosion resistant option for handpumps, but SS may be the best option financially when considering maintenance costs long-term. “Steel pumps have the additional advantage that they are less vulnerable to the sort of shock loads sometimes imposed during loading and unloading in developing countries.” However, SS is heavier, which can be an issue when replacing pipes [31]. Figure 7 shows SS handpump components.
The Handpump Technology Network (HTN) conducted a study on corrosion of stainless steel. Baumann recommended using AISI 316 SS instead of AISI 304 SS pipes, because AISI 316 proved to be more corrosion resistant and to have more tensile strength. HTN could not guarantee the sustainability of a SS solution because they could not guarantee that spare parts would be available or that communities would be able to finance repairs [32].

2.2.3 Polyvinylchloride (PVC)

PVC is also a corrosion resistant option, but it is only applicable at certain depths. A pilot project conducted by HTN introducing PVC as a down-hole component reported PVC to be, “very notch-sensitive. Applications with threaded joints have not been used at deep installations with good results” [32]. In 1989 the IRC stated that PVC rising mains could be successfully implemented at depths of
around 30 m. There are several benefits to using plastic parts: they are corrosion resistant, lighter weight providing ease of maintenance, generally can be mass-produced, and are not as expensive as stainless steel [31]. However, the number of breakdowns with PVC rising mains when compared to SS rising mains will most likely be higher. HTN estimated the lifetime of PVC to be no more than 8 to 12 years [32].

The use of un塑料ised polyvinylchloride (uPVC) riser pipes is recommended when constructing a U3M handpump [17], [33]. In 1989 the IRC also included uPVC as a material that could be successfully implemented as rising mains to depths of around 30 m [31]. In 2001, SKAT and HTN released specifications for the U3M handpump recommending implementation of uPVC for depths of 10-45 m [34]. When deciding between PVC and uPVC for potable water applications, it is recommended that uPVC be used, since uPVC does not contain phthalates or BPA and is more rigid and durable than PVC [35], [36].

2.3 Water Quality

The Uganda National Bureau of Standards (UNBS) is responsible for creating and maintaining national standards, including water quality standards and water monitoring standards [16]. The UNBS provides drinking water standards for Class I and Class II sources (defined in Section 1.2). Class II sources include untreated potable water such as that from boreholes. Class II iron and pH standards are as follows: 1 mg/L iron and pH ranging from 6.5-8.5 [7]. Table 5 compares drinking
water standards set by Uganda and the United States. The USEPA sets primary and secondary regulations for drinking water. Primary regulations must be adhered to; Secondary regulations are not required to be met, but are recommended.

c No more than 5.0% of total coliform testing samples can have a positive result each month.
d 95% of samples must meet this standard in any month. Systems that use conventional or direct filtration may never exceed 1 NTU. Systems using other filtration methods may never exceed 5 NTU.

The Water Resource Monitoring & Assessment Department under Uganda’s Ministry of Water and Environment (MWE) collects water quality data from districts across the country. Water quality data is not available from the Amuru or Gulu
Districts (where water quality data was collected for this research) but it is available from five other districts (Figure 8). The Oyam District was the closest district geographically, bordering the southern region of the Gulu District.

Figure 8. Total iron was analyzed at 203 locations in the Oyam District, just south of the Gulu District.
When a borehole or well is constructed, the Water Resource Monitoring & Assessment Department strongly recommends collecting initial water quality data from the site. Table 6 summarizes groundwater data that was collected in the Oyam District at various sites over time [37]. The average water sample is acidic at a pH of 6.71. However, the majority of iron concentrations measured did not exceed the Guideline Value (GV) or Maximum Acceptable Value (MAV) set for total iron concentration.

The GV for iron is set at 1 mg/L and the MAV at 2 mg/L. The Directorate of Water Resources Management (DWRM) reported that, “Ninety six percent of the concentrations recorded are below 0.8 mg/L. Three boreholes have concentrations between the GV and MAV and 5 boreholes recorded concentrations greater than the MAV” [37]. The distribution of this iron concentration data is displayed statistically and spatially in Figure 9. Further details concerning groundwater quality data can be found in the Oyam District Report.
Figure 9. Total Iron concentration data for the Oyam District (a) statistically distributed (b) spatially distributed
2.4 Pumping Regimes

The MWE manages a Water Supply Database for Uganda. This database includes locations of different water supply types across each district. Water sources in the Amuru and Gulu Districts include protected springs, shallow wells, deep boreholes, rainwater tanks, and public stand posts. Deep boreholes, however, are the most prevalent means of water coverage in the district of Gulu (Figure 10) and the district of Amuru (Figure 11).

![Deep Borehole coverage across Gulu District](image_url)
The Directorate of Water Development (DWD) of the MWE released water coverage information from data collected in districts across the country. It is estimated that 56% of functional water supply technologies in the Amuru District and 54% in the Gulu District are deep boreholes. In the Amuru District 208 of 269 deep boreholes (77%) are functional [40], and in the Gulu District 405 of 511 deep boreholes (79%) are functional [41].

2.4.1 U-Series Handpumps

A majority of the boreholes constructed in Uganda are a variation of the India Mark II hand pump (Figure 12). With the influence of UNICEF, Uganda began the standardization process for the Uganda manufactured India Mark II (U2) in 1995 (US:406:1995). The policy to designate the U2 as the standard handpump for deep
well boreholes (24-50m) in Uganda was adopted in 1999 by the UNBS. The government wanted to create a market for VLOM handpumps that would allow for the accessibility of spare parts across the country [42]. The U2 replaced the non-VLOM Bush pump, and Victoria Pumps Limited became the established U2 manufacturer. The handle of the U2 handpumps was lengthened to closer resemble the Bush pump. Pumps are sometimes imported from India at a lower price and of lesser quality, but the government does little to stop this because of their economic liberalization policy [43].

The modified version of the U2 (U2M) is designed to allow for easier maintenance. The U2M has an open top cylinder (OTC) design and “pumping elements which can be removed without having to lift out the rising main” [27]. The U2 and the Uganda manufactured India Mark III (U3) are the standard shallow well handpumps (3-21 m) (US:405:1995). The difference is the riser pipes: 32 mm nominal borehole (NB) for the U2 and 65 mm NB for the U3 [29]. The modified U3 (U3M) was designed as an alternative to resist corrosion. Materials were modified to include the use of uPVC riser mains and stainless steel or fibre glass reinforced plastic (FRP) connecting rods [17], [33]. The U3M also incorporates an OTC for ease of maintenance and is designed to lift water from depths of 10-45 m [34].
Figure 12. India Mark II Hand Pump Drawing [58]
CHAPTER 3. MATERIALS AND METHODS

Latitude, longitude, and elevation were recorded using the application ‘GPS Location’ offered by V_Firefighter for Android for sixteen borehole sites in northern Uganda (Figure 13). No additional data were collected at borehole 15 because its U2 pump was no longer in working condition. Several different water quality tests were conducted and interviews were used to collect qualitative data from the remaining fifteen boreholes. In addition, observational data were collected at each site.

Figure 13. Locations of 16 boreholes in Northern Uganda from which data were collected.
3.1 Water Quality Testing

Conductivity, total dissolved solids (TDS), pH, and iron concentration were measured at 15 borehole locations in the Gulu and Amuru districts. See Appendix A for details on measurement values recorded from each borehole.

3.1.1 pH Study

The reliability and accuracy of pH strips were compared to measurements recorded by a pH probe. The pH probe (Hanna probe) was considered the reference method for this study. Three different pH strips were used. Details of the probe and pH stripes used are shown in Table 7.

<sup>a</sup>[44]  <sup>b</sup>[45]  <sup>c</sup>[46]  <sup>d</sup>[47]
At each borehole site, four 100-mL water samples were taken within the same pump stroke. Three of the water samples collected were dedicated to a different pH strip type, and pH measurements were conducted in triplicate with each type of pH strip (Figure 14). The fourth beaker of water was used to measure conductivity, pH, and TDS with the Hanna probe. A three-point calibration curve was performed daily for the portable probe using commercial buffers of pH = 4, 7, and 10.

*Figure 14. From left to right: Youth Waters, Extended Range, MN pH test strips in triplicate (Photo courtesy of Jake Carpenter)*

### 3.1.2 Iron Concentration

The iron concentration at each borehole was measured using the SenSafe™ Iron Check test kit. A water sample was collected from the pump and appropriately diluted; iron concentration was then quantified using the procedure provided by the
manufacturer (Figure 15). The SenSafe™ strips allowed iron concentrations to be quantified from 0.1-5.0 ppm (mg/L) with a detection sensitivity of 0.1 ppm (mg/L).

Figure 15. L: 30 seconds of gentle stirring followed by a 2-minute wait time with the strip removed from the sample. R: Matching strip to closest color on the container. (Photos courtesy of Jake Carpenter)

3.2 Pump Tests

Two types of pump tests were performed—a pump performance test and a WaterAid pump test. These tests provide information on the efficiency of the pump and the characteristics of borehole water quality, respectively. The borehole sites where these tests were completed are specified in each of the following subsections.

3.2.1 Pump Performance Testing – Leak Test (Two Minute Stroke Test)

A pump performance, or leakage test [48], was completed at 12 of the 15 borehole sites. This test was conducted by first fully priming the pump. Once primed, pumping was suspended for two minutes. After the 2-minute wait period,
the user would pump until water flowed from the pump spout. The number of pump strokes required to reach this point was recorded. Ideally this number would be one. Anything greater than one may be an indication of a leak, which typically occurs as a result of “worn rubber components in the cylinder, leaking rising main joints or severely corroded riser pipes” [48].

3.2.2 WaterAid Pump Test

Pump tests were performed following the WaterAid pump test method (Appendix B) to determine if the origin of iron is naturally occurring in the groundwater or related to the corrosion of the pump components [49]. The reader should take note that the radius equations in the WaterAid pump test method document are incorrect. Calculate the radius by multiplying the diameter by 0.5 or dividing the diameter by 2 (r=d*0.5=d/2).

Two sites were tested—boreholes 14 and 16 (Figure 13). At each site, community members were asked to estimate the number of jerry cans that had already been pumped on that day. An initial sample was taken, the start time was recorded, and the iron concentration, pH, conductivity, and TDS were measured. For every subsequent 20 L of water pumped the time was noted and the pH, conductivity, and TDS were measured using the Hanna probe (Figure 16). Iron concentrations at borehole 14 were measured every 20 L up to 160 L and every 40 L from 160-320 L.
Figure 16. Measuring pH, conductivity, and TDS with the Hanna probe during a pump test at borehole 16.

At borehole 16, two pump tests were conducted. For the first pump test, 1000 L were pumped and iron concentrations were measured every 100 L. During the second pump test, 2400 L were pumped and iron concentrations were measured at 800, 1000, and 1100 L, and every 200 L from 1200-2400 L. The raw data from these tests can be found in Appendix C.

3.3 Observational and Qualitative Data Collection

Several observations were made at each borehole site including determining a landmark to identify the location of the borehole, the pump type, the pump’s condition and any repairs that may have been made, the drainage conditions, and approximately how old the borehole may be. Nearby community members were also asked about the usage patterns of the borehole, the estimated amount of water pumped so far that day, who the primary users of the pump are, the quality of the
water, whether the soap lathers, and if there had been any repairs made, by whom, and when.

3.4 Analysis Methods

Geographical and statistical methods were used to analyze the data collected in Uganda. The three main programs used during this analysis were ArcMap 10.1.4, Microsoft Excel, and Minitab® 16.2.4. Several maps were created and an initial difference method comparison and paired t-tests were performed on the data collected.

3.4.1 ArcGIS

ArcMap 10.1.4 was used to create Figures 8, 13, 24. A shapefile from Global Administration Areas (GADM), version 1.0, downloaded from DIVA-GIS, was used in creating Figure 8. The shapefile contained district boundaries of Uganda [50]. Uganda continues to rezone districts. Highlighted districts were modified as necessary to match the most recent district zoning.

Figure 8 in Section 2.3 displays the districts where water quality data was available from the MWE. Figure 13 in Section 4.2.2 maps all of the borehole locations. Figure 24 in Section 5.2.2 maps the measured iron concentration (mg/L) at each borehole.
3.4.2 Statistical Analysis

Two types of statistical analysis were used to investigate the pH data collected at each borehole. Paired t-test and Bland-Altman difference method analyses were performed to compare the Hanna probe measurements to each of the pH test strip measurements. Minitab® 16.2.4 and Microsoft Excel were used in performing the analysis methods.

A paired t-test is performed when measurements are paired in order to minimize differences in measurement due to technician, weather or seasonal conditions, time, etc. Conducting a paired t-test, as opposed to an independent t-test, eliminates variation due to uncontrollable experimental factors. Experiments are designed to ensure that uncontrollable and unknown factors contribute equally to each measurement. The average of paired differences, \( \bar{d} \), is analyzed in a paired t-test:

\[
\bar{d} = \frac{\sum d_i}{n} = \frac{1}{n} \sum (y_{1,i} - y_{2,i}) \quad \text{Equation 6}
\]

where \( y_1 \) and \( y_2 \) are random variables observed as matched pairs and \( n \) = number of paired observations.

The standard deviation of the differences, \( s_d \), and the standard error of the average difference, \( s_{\bar{d}} \) (Equations 7 & 8) are calculated in order to determine the 1-\( \alpha \) confidence interval for \( \delta \) (Equation 9) [51].
\[ s_d = \sqrt{\frac{\sum (d_i - \bar{d})^2}{n-1}} \]  
Equation 7

\[ s_d = \frac{s_d}{\sqrt{n}} \]  
Equation 8

\[ \bar{d} - s_d t_{n-1, \alpha/2} < \delta < \bar{d} + s_d t_{n-1, \alpha/2} \]  
Equation 9

\( \delta \) is defined as the true mean of differences between the two pH measurement methods observed. \( \bar{d} \) is an estimate of the true mean difference (\( \delta \)). For the three paired t-tests conducted \( \alpha = 0.05 \).

The Bland-Altman difference method is used to analyze the difference in measurement techniques by comparing the difference in methods to the average of the methods. An initial analysis of the data includes directly graphing each pH test strip versus the Hanna probe. A line of equality is included in the initial plot. The second plot in the Bland-Altman method compares the difference in measurement techniques (Probe-Test Strip) to the average of the methods\([\text{Probe} + \text{Test Strip})/2\]. The mean difference \( \pm 2 \) standard deviations is also indicated in the second plot. Graphically displaying this information can help reveal any bias or trends in the data that are not always evident in the first plot of pH strip versus Hanna probe [52]. Ideally the results and conclusions from the Bland-Altman method will match the results from the paired t-tests and will help to further distinguish between the three
pH test strip methods. The Bland-Altman method is used as a supplementary analysis to the paired t-tests [53].

There are many different techniques to compare measurement methods, each applicable under certain circumstances. Literature is unclear whether any one technique is best. It is disputed whether correlation or regression analyses, difference of means or the Bland-Altman plot are appropriate to use when comparing measurement methods [54], [55]. The Clinical and Laboratory Standards Institute (CLSI) suggests plotting the difference in methods versus the standard method (the golden standard or reference method) [56]. Bland and Altman specifically defend why differences in methods should be plotted versus the average of the methods instead of versus the standard method. Plotting versus the latter will always show a relationship between the difference and magnitude even if there actually is none [57].
CHAPTER 4. FIELD RESULTS AND DATA ANALYSIS

Quantitative and qualitative data collected and data analysis and interpretation from each borehole are presented in this chapter. Observational and qualitative data collected – pump type, condition of the pump, any repairs made, drainage conditions, borehole age, usage patterns, quality of water, etc. – are provided in Appendix A.

4.1 pH Analysis

An initial analysis of the pH data collected from the three different pH test strips and the Hanna probe was conducted by performing paired t-tests. Additional statistical analysis was completed using the Bland-Altman method and compared to the findings from the initial analysis. The second analysis further distinguished between the three pH test strips.

4.1.1 Paired t-Tests

pH strips from three different vendors (refer to Table 7) were used to test the pH at 15 boreholes. As shown in Table 8, the results indicate that only the Youth Waters strips were statistically different from the Hanna probe. The MN and Extended Range strips were both indistinguishable from the probe at $\alpha=0.05$.

\(^a\)Extended Range, \(^b\)Youth Waters

The Youth Waters measurements consistently underestimated the pH when compared to the Hanna probe measurements. See Appendix D for further details from each paired t-test.

4.1.2 Bland-Altman Difference Method

*Figure 17* shows good agreement between the Hanna probe and the MN test strips, which confirms the t-test results. The Extended Range test strip measurements are not as randomly distributed as the MN test strips, but still appear to agree with the reference method (*Figure 18*). Readings between 6.0 and 7.0 pH are more accurate than readings outside of this range for the Extended Range test strips. pH levels below 6.0 were underestimated by the Extended Range strips. The one instance where pH was above 7.0 was overestimated using the Extended Range test strip. More measurements need to be taken to determine if these trends hold.

As shown in *Figure 19*, the Youth Waters test strips consistently underestimate the pH compared to the Hanna probe measurements. The Youth Waters measurements are the most precise of the three test strips (SD of
difference=0.17), but it is not clear from these graphs if the Youth Water strips are an acceptable replacement for the reference method.

The mean difference of the MN test strips is smaller than that of the Extended Range test strips (mean difference = -0.03 and 0.18, respectively). The standard deviation of the difference in MN test strips versus the Hanna probe is also smaller than the standard deviation of the difference in Extended Range test strips versus the Hanna probe (SD=0.26 and 0.32, respectively). This suggests that the MN test strip is more accurate than the Extended Range test strip.
Figure 17. Comparison of the MN pH test strip to the Hanna probe reference method from the measurement of pH in 15 boreholes in the Amuru and Gulu Districts of Northern Uganda. (A) Comparing methods with a line of equality ($y=x$). (B) The Bland-Altman plot with $\pm 2$ standard deviations from the mean difference (dashed lines) and line of equality (solid line). Mean difference= -0.03. SD= 0.26.
Figure 18. Comparison of the Extended Range pH test strip to the Hanna probe reference method from the measurement of pH in 15 boreholes in the Amuru and Gulu Districts of Northern Uganda. Mean difference = 0.25. SD = 0.17.
4.1.3 pH Correlations

At 11 of the boreholes, women of the community that were collecting water during water sampling were asked to approximate the number of jerry cans of water that had already been pumped that day. The relationship between pH and the estimated number of jerry cans pumped can be linearly modeled as:

\[ \text{pH} = 6.6 - 0.0066J, \quad R^2 = 0.43 \]

Equation 10

where \( J \) = number of jerry cans. See Figure 20. These data suggest that with continued pumping of the borehole, pH decreases.

Figure 20. There is a negative linear relationship between the pH and the number of jerry cans pumped.
4.2 Iron Concentration

Iron concentration was analyzed quantitatively and geographically at the 15 borehole sites. Eleven of the fifteen boreholes (73%) met the UNBS, Class II standards set for iron concentration (1 mg/L) (Table 5) [7].

4.2.1 Iron Concentration, Number of Jerry Cans Pumped, and Time

Iron concentration, the estimated number of jerry cans pumped, and the time of day were compared to determine a relationship between each. There is no discernible correlation between iron concentration and time of day (Figure 21) or the estimated number of jerry cans pumped and the time of day (Figure 22).

![Figure 21](image)

*Figure 21. A relationship between the logarithmic of iron concentration and the time of day cannot be deducted.*
Figure 22. A relationship between the logarithmic of the number of jerry cans pumped and the time of day cannot be deducted.

However, the relationship between iron concentration and the estimated number of jerry cans pumped can be linearly modeled as:

\[
\log(\text{iron conc. (mg/L)}) = -1.73(\log(J)) + 2.45, \quad R^2 = 0.68
\]

Equation 11

where \( J \) = number of jerry cans. See Figure 23. As the number of jerry cans pumped increases, the iron concentration decreases. This relationship suggests that the iron levels in the boreholes tested were at least partially due to corrosion. Langenegger et al. observed similar trends in their research of iron concentration in boreholes in Ghana [18], [19], [27]. They observed that as more water was pumped, the iron levels dropped and stabilized.
Figure 23. A relationship between the logarithmic of iron concentration and the number of jerry cans pumped can be deducted.

4.2.2 Geographic Iron Concentration

ArcGIS was used to map iron concentrations measured at 15 borehole sites (see Figure 24). The farther the borehole site from a main road, the higher the iron concentrations. This observation may be related to usage. Boreholes that are further from main roads may not be used as frequently. The idea that higher iron concentrations are measured at boreholes that are less frequently used is similar to previous findings that the more jerry cans pumped, the lower the iron concentration. Langenegger explains,

"Field experience suggests that handpump equipped water points having an iron concentration of more than 5 mg/L are generally little used. The iron concentration can be taken as an indicator of handpump use where corrosion is a problem"[18].
The iron concentrations in boreholes 10 and 16 were 20 mg/L (see raw data in Appendix A). From interviews conducted on site: Many prefer unprotected springs as their water source to borehole 16; and borehole 10 is used only for washing; families collect their drinking water from a nearby spring instead.

Figure 24. Iron Concentrations measured at 15 sites in the Amuru and Gulu Districts.
4.3 Pump Performance Tests – Leak Test (Two Minute Stroke Test)

The pump performance of twelve of the sixteen identified boreholes was evaluated (Table 9). The Swiss Centre for Appropriate Technology (SKAT) and the Rural Water Supply Network (RWSN) suggest priming the pump and waiting 30 minutes before counting the number of pumps required for water to flow. It should be noted that pump performance testing at each borehole deviated from this suggestion. The wait time observed was two minutes instead of thirty minutes. When following SKAT and RWSN suggestions, in order for a borehole to pass the test the number of pumps after the borehole was primed must be 10 or less [48]. Nine boreholes (75%) passed under these conditions. Five boreholes (42%) only required one pump stroke. The average number of pumps after priming the borehole was 11, and the standard deviation was 18 pumps. Three boreholes required more than 10 pumps. This indicates that 25% of the boreholes are not working efficiently. Leaking could be due to “worn rubber components in the cylinder, leaking rising main joints or severely corroded riser pipes” [48].
The results from each pump test are analyzed in two parts: Part A—iron concentration and pH and Part B—conductivity and TDS.

The pump test for borehole 14 suggests that iron concentrations can be attributed to the corrosion of pump components because the iron concentration drops rapidly in the beginning of the test [49]. For example, initial iron concentration was measured as 10 mg/L and after 320 L of water was pumped, the iron concentration was 1 mg/L, showing a drop in concentration of an order of magnitude. The pH for borehole 14 stayed between 6.0 and 6.5 throughout the pump test (Figure 25). These results suggest that the iron concentration observed at
borehole 14 is mostly attributed to corrosion. In *Groundwater Quality and Handpump Corrosion in Africa*, Langenegger concluded that iron concentrations in groundwater do not typically exceed 1 mg/L naturally [19]. Therefore the 1 mg/L stabilized iron concentration in borehole 14 is most likely a result of the groundwater geography.

The data collected from all three pump tests confirmed that conductivity and TDS are directly related (*Figures 25B, 26B, and 27B*). If conductivity or TDS increases, the other increases, and vice versa. For borehole 14 (*Figure 25B*), as more water was pumped, the conductivity and TDS decreased until they leveled off around 0.15 mS/cm and 115 ppm, respectively. Conductivity and TDS trends seem to correspond with the iron concentration levels for each pump test.

Two pump tests were conducted for borehole 16. The iron concentrations during the first pump test conducted on borehole 16 (Pump Test 1) decreased from an initial value of 12.5 to 2.33 mg/L, but never stabilized. The initial pH was 7.0, but stabilized at 6.2 after 480 L had been pumped (*Figure 26A*). For borehole 16-Test 1 (*Figure 26B*), as more water was pumped conductivity and TDS decreased (excluding the initial measurement) until they leveled off around 0.17 mS/cm and 128 ppm, respectively, after 600 L had been pumped.

The iron concentrations measured during the second pump test for borehole 16 (Pump Test 2) was initially 30 mg/L and stabilized at 2 mg/L after 2400 L of water was pumped. As with Pump Test 1, the initial pH of Pump Test 2 was 7.0, but stabilized at 6.2 (*Figure 27A*). This trend may be attributed to the Kuch mechanism[22]–[24]. A product of the Kuch mechanism, hydroxide, could increase
the pH of the water as it sits overnight. Once dissolved oxygen is reintroduced to the bulk water by pumping, ferrous iron is converted to ferric iron causing the initial red color of the effluent. The pH drop observed in Pump Tests 1 and 2 of borehole

Figure 25. Borehole 14 pump test results (A) pH stabilizes around 6.15 and iron concentration stabilizes at 1.0 mg/L. (B) Conductivity and TDS stabilize at 0.15 mS/cm and approximately 114 ppm, respectively.
16 is a result of the borehole being flushed. The stabilized pH is representative of the groundwater source. For borehole 16-Test 2 (*Figure 27B*), conductivity and TDS stabilized around 0.17 mS/cm and 127 ppm, respectively.

Results from the two pump tests at borehole 16, when compared to pump studies performed by the UNDP-World Bank Water and Sanitation Program and Langenegger, suggest that the iron concentration levels in borehole 16 are mostly caused by corrosion [18], [19], [27]. The 2 mg/L stabilized iron concentration is most likely a result of the groundwater geography.

A complaint of the community at borehole 16 was that the water turned black when boiled. This phenomenon was observed at pumped volumes of 0.1, 260, and 680 L (iron concentrations of 12.5, 9.5, and 5.9 mg/L, respectively) (*Figure 28*). As a sample from the borehole was boiled, iron cations were released into solution. At an iron concentration of 12.5 mg/L, the final product of boiled water was dark and cloudy. As the iron concentration decreased, the darkness and cloudiness of the water lessened. At an iron concentration of 5.9 mg/L the final product of the boiled sample was still not clear enough to be deemed aesthetically acceptable. As a result, many families prefer collecting water from an unprotected spring than from the borehole, although the spring water is much more likely to contain biological contaminants.
Figure 26. Borehole 16 Test #1 pump test results (A) pH stabilizes at 6.2 and the last iron concentration measurement taken equals 2.33 mg/L. (B) Conductivity and TDS stabilize at 0.17 mS/cm and 128 ppm, respectively.
Figure 27. Borehole 16 Test #2 pump test results (A) pH stabilizes at 6.2 and iron concentration stabilizes at 2.0 mg/L. (B) Conductivity and TDS stabilize at 0.17 mS/cm and approximately 127 ppm, respectively.
Figure 28. As the iron concentration in the sample decreased the final darkness and cloudiness of the boiled sample lessened. (left to right: 12.5, 9.5, 5.9 mg/L of iron at 0.1, 260, and 680 L pumped)
CHAPTER 5. CONCLUSIONS AND RECOMMENDATIONS

5.1 Conclusions

This research investigated the origins of iron concentration in boreholes, pH measurement methods, and corrosion resistant advances in handpump design. The following conclusions were made.

pH is an important indicator of the aggressivity of groundwater. Three pH test strips were compared to a Hanna probe in order to determine if any of the three could replace the Hanna probe as a reliable, cost-effective option. Statistical analysis using paired t-tests and the Bland-Altman difference method suggests that the MN and Extended Range test strips are statistically acceptable options for measuring pH at boreholes in Northern Uganda. Due to their low cost and ease of use, MN test strips are recommended if accessible.

Results from Pump Tests at boreholes 14 and 16 suggest that much of the iron observed in borehole water pump effluent is from corrosion. A similar conclusion is drawn from Figure 23 that plots iron concentration with respect to the estimated volume of water pumped from the borehole prior to sampling. These data suggest that at boreholes where red or cloudy water has been observed in the morning, it is recommended that the user pump approximately 100 L or 12 minutes before collecting any water that day [18], [19]. This should be repeated daily.
This will help to ensure that most of the iron build-up from overnight is flushed out before collection begins. At the least, the user should understand that iron concentration decreases as pumping volume increases. This method will temporarily address high iron concentrations in boreholes, but further investigation may be necessary to determine if rehabilitation of the pump is necessary.

The district water authority and any other applicable personnel should consider the following parameters when determining whether a borehole should be rehabilitated: iron concentration, pH of groundwater, and electroconductivity [19], [27]. It would be valuable to conduct a WaterAid pump test to better understand the origins of the iron levels [49]. Measuring the pH during this test will also help indicate the corrosivity of the groundwater. If (1) the iron concentration is high at a borehole, (2) the pump test suggests the high iron concentration does not originate from the groundwater, and (3) the water is identified as aggressive based on pH, then the user should consider replacing pump parts with corrosion resistant materials. Electroconductivity predicts the potential for electrochemical or galvanic corrosion [19], and can be an indicator of iron particulate in the water.

5.2 Recommendations to Field Workers

Field workers in the development sector can use the findings from this research to improve their water quality studies and borehole rehabilitation and corrosion prevention efforts. The following items should be noted:
• Literature and this work show a correlation between aggressive groundwater and GI pipe and U2 pump corrosion [18], [19], [27].

• Boreholes will continue to be abandoned unless methods are implemented to reduce iron concentration levels. High iron concentrations become an acceptability issue for user [16], [19].

• pH of groundwater is a good indicator of its corrosivity and the potential for corrosion of well casings, riser pipes, and handpumps [18], [19].

• Dissolved oxygen, alkalinity, hardness, temperature, TDS, electroconductivity, ammonium [19], calcium, chloride, and sulfate concentrations can give insight into the source of iron in a borehole [6]. If corrosion is the source of the iron, dissolved oxygen can help determine if the Kuch mechanism is a contributor to the iron concentration [22]–[24]. Electroconductivity can help predict electrochemical and galvanic corrosion in handpumps, and ammonium can indicate the presence of iron related bacteria in a borehole [19].

• pH test strips are an inexpensive method for reliably measuring the pH (see Table 7). This study found the MN test strips to be in close agreement with the Hanna probe measurements. The Extended Range test strips were also determined to be a statistically acceptable replacement for the Hanna probe.

• Before installing borehole equipment, the pH of the groundwater should be measured. When the aggressivity of groundwater is defined as medium to heavy based on pH [18](Table 2), PVC or stainless steel pipes should be used.
Deciding between PVC and SS will depend mostly on technical considerations and the availability of materials and funding for the materials. If possible, follow recommendations made for U3M handpumps, which are specifically designed to be corrosion resistant [17].

- When boreholes are first constructed thorough pump testing should be completed to provide a baseline [37].
- Use pump performance test results and pH measurements to determine if rehabilitation is needed for existing wells. A pump performance test can indicate if there is leaking in the borehole because of severely corroded well components [48]. WaterAid recommends pumping at least one well volume, preferably two, in order to accurately determine the characteristics of the groundwater [49]. If the groundwater is defined as aggressive based on the Langenegger pH Index [18](Table 2) then the pipes should be replaced with PVC or SS based on technical considerations and the availability of funds and materials. If possible, follow recommendations made for U3M handpumps, which are specifically designed to be corrosion resistant [17].

5.3 Recommendations for Future Work

Future work focused on understanding the aggressiveness of groundwater in Northern Uganda and on improving borehole and handpump performance should consider adding the following to the methods outlined in this document:
• Repeat the current study for reliability and validity of pH strips for use in Northern Uganda using pH test strips that are readily available in the Gulu area. Identify a local supply chain and the cost of available pH strips.

• Measure dissolved oxygen (DO). Take continuous readings during pump testing after an overnight stagnation period. Use this data to further investigate whether the Kuch Mechanism is a contributing factor to the observed increase of pH in the borehole overnight or during periods of stagnation [22]–[24].

• Measure ammonium concentration to determine if iron related bacteria are a contributor to iron concentrations in the borehole [19].

• Measure alkalinity, hardness temperature, calcium, chloride, and sulfate concentrations to gain further insight into the source of iron in boreholes [6].

• Identify the cost of all pipes available in the Gulu area supply chain and note their composition.

Experiments should be designed so that the same statistical analysis can be conducted using paired t-tests and the Bland-Altman method to determine the most valid, reliable, and cost effective pH test strip.

Further investigation into the composition of the GI pipes that are available in the Gulu area is also recommended. The galvanized layers could be of varying qualities and compositions. Determining the makeup of the material could help explain why the pipes are corroding so quickly.

</tbody>
</table>
Water quality testing to establish whether high iron originates from corrosion of pump components or the aquifer

The Problem:

(1) Production of a red/brown coloured discharge first thing in the morning. This is caused by the discharge of corrosion products that have accumulated in the well during the night when there was no pumping. In most cases, the discharge clears up as the solid corrosion products are removed from the well.

(2) Discolouration of water which was clear when pumped, but develops a red/brown discolouration after a few minutes to hours. This is the result of the oxidation of ferrous iron (Fe$^{2+}$) to ferric iron (Fe$^{3+}$), which causes the precipitation of iron hydroxides and oxides. This could be caused by either naturally high ferrous iron in the aquifer, or the addition of iron to the well water from corrosion of handpump components.

Some wells may produce a red coloured discharge that does not clear after several hours of pumping. This does not necessarily indicate a problem with high iron, rather it is likely to be caused by poor well development, a badly positioned screen, or poor quality gravel pack, resulting in entry of fine clay or silt particles from the aquifer into the well. The well is likely to be unacceptable in this condition and requires further development to ensure clear water is produced.

Test for origin of iron:

To identify if corrosion of pump components is the cause of high iron concentrations, a simple pumping test can be carried out with periodic measurements of iron content. If iron concentrations fall rapidly after a few minutes (see graph below), corrosion is likely to be the major source of iron. The objective of the pumping is to replace the well water with fresh water from the aquifer so that iron concentrations are representative of the aquifer water.

The test should be undertaken first thing in the morning, before any pumping has taken place.

Example from a test on a non-corrosion resistant pump, West Africa (after Langenegger, 1994):

Total iron concentration vs quantity pumped.

$V_1$ = volume of rising main

$V_2$ = volume of well

Most of the solid corrosion products will be removed once the water within the rising main has been removed, volume $V_1$ on the graph.
APPENDIX B (continued):

**Calculate volume of rising main (V₁) using:** \[ 3.1415 \times r^2 \times h \times 1000 \text{ litres} \]

Where: \( h = (\text{RM}) - (\text{WL}) \) and \( r = d/0.5 \)
- Length of rising main, RM (m) From pump installers report
- Depth of water table, WL (m) From drillers report, or borehole dip before the test
- Diameter of rising main, d (m) Take as 0.05 m (2 inches)

The length of test depends on the well volume, as you should aim to pump at least 1 well volume (point \( V₂ \) on the graph), but preferably 2 well volumes, to ensure fresh aquifer water has started to enter the well.

Details of the borehole construction required to calculate the well volume will be contained in the drilling report. Borehole and casing diameters are usually recorded in millimetres and must be converted to metres for the calculations. It is suggested that all the calculations are undertaken in the office prior to the test.

**Calculate the total volume of water in the well (V₂):**

Boreholes are usually drilled at several diameters and these need to be taken into account when calculating the well volume.

\[ \text{Volume} = 3.1415 \times r^2 \times h \times 1000 \text{ litres} \]

**Volume in casing 1:**
- \( h = \text{Depth to base of casing 1 (D1)} - \text{WL} \)
- \( r = \text{Casing 1 diameter} \div 0.5 \)

**Volume in casing 2:**
- \( h = \text{Depth to casing 2 (D2)} - \text{D1} \)
- \( r = \text{Casing 2/borehole diameter} \div 0.5 \)

Add the calculated volumes to get the total well volume.

Either measure pumping rate or assume 12 - 18 litres/minute (India MKII)

**Minimum pumping time** (\( V₂ \)) = well volume (litres) \div pumping rate (litres/minute)

**Recommended pumping time** 2 well volumes.

Concentrations of iron can be measured with the Wagtech Comparator and the requisite reagents. It is important to note that a highly coloured or turbid sample is likely to give incorrect results.

Samples should be tested immediately after they have been taken as dissolved iron may begin to precipitate giving inaccurate results for the true iron content.

If possible, pH and electrical conductivity (EC) should be measured at the same time.

As more water is pumped from the well, smaller and smaller changes in iron concentration will be observed (See graph) and the time between sample testing can be increased.

For each sample, record:
- Time of sampling (since start of pumping)
- Volume abstracted - calculated (litres)
- Iron concentration (mg/l) (also pH and EC)

Sampling frequency:
- Up to 6 samples
- 1st sample at or just after \( V₁ \)
- 4th sample at \( V₂ \)
- Further samples up to 2 well volumes

This method was commissioned by WaterAid and prepared by Lawrence Brown.
